Acknowledgments

We would like to thank the Intelligent Transportation Systems (ITS) Institute, University of Minnesota, for supporting this project. The ITS Institute is a federally funded program administrated through the Research & Innovative Technology Administration (RITA). We would also like to thank the Minnesota Traffic Observatory for hosting this research project, providing material and software support. Finally, we would like to acknowledge the importance of the data sets generated and maintained by the Next Generation SIMulation (NGSIM) community. This is one of many research projects these unique datasets have made possible.

Executive Summary

Travel time estimation and prediction on urban arterials is an important component of Advanced Traveler Information Systems (ATIS) and Advanced Traffic Management Systems (ATMS). Although great progress has been achieved in ATIS and ATMS, reliable and efficient estimation of travel time is still not a wide-spread accomplishment especially on arterials because it requires extensive sensor infrastructure normally found only on freeways. Since it is cost prohibitive to install location-based sensors on all arterial roads in large urban networks, this study aimed in using the information of the global positioning system (GPS) probes to augment less dynamic but available information describing arterial street travel time. The direction followed in this project chose a cooperative approach to travel time estimation using static information describing arterial geometry and signal timing information, and semi-dynamic information of historical travel time distributions per time of day, and utilized GPS probe information to augment and improve the latter. The objectives of this study focused on developing a methodology to characterize arterial travel time patterns by travel time distributions, proposing methods for estimating such distributions from static information and refining them with the use of historical GPS probe information, and given such time and location-based distribution, using real-time GPS probe information to produce accurate path travel times as well as monitor arterial traffic conditions.

First, travel time patterns of signalized arterial links were analyzed based on travel time histograms. The work mainly focused on through-through vehicles. From this subset of vehicles, four travel time states were defined: non-stopped, non-stopped with delay, stopped, and stopped with delay. Second, link travel time distributions were approximated using mixtures of normal densities. If prior travel time data is available, travel time distributions can be estimated empirically, using the EM algorithm. Otherwise, travel time distribution can be estimated based on signal timing information and geometric structure of the arterial. Third, link travel time was extended to produce route travel times. Because travel times on successive links are not independent, a Markov Chain based model was proposed to capture the potential relationship of travel time between consecutive links. Empirical examples showed the estimated route travel time by the Markov Chain model was very accurate with errors of less than 2%.

GPS travel time data is used to predict the travel time by identifying the traffic condition. The traffic condition identification approach was developed based on Bayes Theorem. Results showed that in most cases, one GPS sample was enough to discriminate between the two traffic conditions. Compared to other approaches, the proposed method needs much less real-time information. Moreover, these GPS data could also be used to update the parameters of the travel time distributions using a Bayesian update. The iterative update process makes the posterior travel time distributions more and more accurate.

Finally, two comprehensive case studies using the Next Generation SIMulation (NGSIM) Peachtree Street dataset and GPS and simulation data of Washington Avenue in Minneapolis, MN were conducted. The first case study estimated prior travel time distributions based on signal timing and geometric structure under different traffic conditions. Travel time data were classified into different traffic conditions and corresponding distributions were updated. In addition, results from the Bayesian update and EM algorithm were compared. Overall, the EM algorithm fit the

data better than Bayesian update. However, in some scenarios the Bayesian approach could reflect the real world situation when some data was missing.

The second case study first tested the methodologies based on real GPS data collected for studying the traffic flow pattern change of the opening of the replacement I-35W Mississippi River Bridge. After which, a methodology was proposed to distinguish new traffic conditions. In order to differentiate traffic conditions under same signal control by volume, a microscopic simulation model was built. Utilizing the GPS probe information from simulation, three different traffic conditions were identified during morning peak hour.

Chapter 1 Introduction

Travel time is a crucial variable both in traffic demand modeling and for measuring network performance. In traffic demand modeling, travel time determines the route choice and trip distribution. From the network performance measurement point of view, travel time implies the congestion level and is the most direct traffic information to general road users. Therefore, how to estimate or predict travel time accurately has been one of the most popular topics in transportation engineering.

Today, travel time estimation and prediction on urban arterials is an important component of Advanced Traveler Information Systems (ATIS) and Advanced Traffic Management Systems (ATMS). Although great progress has been achieved in ATIS and ATMS, reliable and efficient estimation of travel time is still not a wide-spread accomplishment especially on arterials since it requires extensive sensor infrastructure normally found only on freeways. Since it is cost prohibitive to install location-based sensors on all arterial roads in large urban networks, this study like several others planned in capitalizing on another type of sensor information; the GPS based, mobile sensors. Unlike others though this study did not want to end up with a methodology or procedure feasible sometime in the future when enough GPS probe vehicle are roaming the streets. Instead, this study aimed in using the information of the GPS probes to augment less dynamic but available information describing arterial street travel time.

1.1 Project Objectives

The direction followed in this project choose a cooperative approach in travel time estimation using static information describing arterial geometry and signal timing information, semi-dynamic information of historical travel time distributions per time of day, and utilizes GPS probe information to augment and improve the latter. The objectives of this study focused on developing a methodology to characterize arterial travel time patterns by travel time distributions, propose methods for estimating such distributions from static information and refining them with the use of historical GPS probe information, and given such time and location-based distribution use real-time GPS probe information to produce accurate path travel times as well as monitor arterial traffic conditions.

1.2 Background

Travel time estimation could be roughly divided into freeway travel time estimation and arterial travel time estimation. This report only focuses on arterial travel time estimation. Several analytical models (Spiess, 1990; Xie *et al.*, 2001; Skabardonis and Dowling, 1997; National Research Council, 2000; Bureau of Public Roads, 1964) were proposed which relate arterial link travel time to traffic volume. Even with signal timing and volume information, these models can only provide the average travel time for all vehicles and are generally used in planning applications. In reality, different cluster of vehicles' travel time behave very differently. The average value couldn't reflect different components of travel time. Therefore, a travel time distribution from which performance measures such as the mean travel time, or the standard deviation can be derived, is preferred.

In order to estimate the arterial travel time distribution, travel time information for individual vehicles is required. One feasible way to collect travel time data is from the monitoring systems. In the United States, most urban freeways are now equipped with sensor systems that allow real-time monitoring of traffic conditions. These generally consist of a combination of pavement based sensors and video detectors, and can be used to identify breakdowns in the traffic flow as well as estimate travel times on the freeway system. For urban arterial systems however the ability to monitor traffic conditions and estimate travel times has lagged behind what is done on freeways. This is in large part due to the complexity of urban traffic environment. For example, up to the year 2009 the Twin Cities metro area of Minnesota had approximately 18,638 lanemiles of urban arterial (Minnesota DOT, 2009, 2010). Simply providing loop detectors at a density of 1 detector every 0.5 lane-mile (similar to the density on freeways) would require more than 37,000 detectors. Moreover, a great number of arterial links are less than 0.5 mile in length, this in turn increases the number of detectors needed for monitoring the arterial system.

These difficulties have led to an active interest in monitoring urban arterials using already-deployed sensors. One interesting possibility is to use probe vehicles. Certain types of vehicles, such as taxies or buses, which are easier to monitor have been suggested as probe vehicles (Dailey, 2002). However, using special purpose vehicles has disadvantages. Buses have to stop at each bus stop which overestimates travel times while taxis behave differently when they are empty or full. As a result, they are not able to represent the driving behavior of general road users. Recently, the increasing availability of vehicles which can access the global positioning system (GPS) and the development of wireless telecommunication technologies, have permitted general road users to serve as probes. In principle, a steadily increasing number of GPS-equipped vehicles could lead to reliable, accurate travel time. Information transmitted from those GPS probe vehicles not only can help calculate travel time distributions on arterials, but also provides real-time traffic condition information.

The main difficulty with reliance on probes is that the travel time provided by a single probe is essentially a sample, of size one, from the prevailing distribution of travel times. This leads to questions regarding the density of probes needed to produce useful sample sizes. Currently, GPS equipped vehicle density is quite low, moreover GPS can only provide information regarding the link it currently resides on. Therefore, rather than attempt to estimate the travel time distribution from scratch, it may be possible to combine limited information from GPS probes with prior knowledge from signal timing and arterial geometry information to reconstruct the travel time distribution.

1.3 Literature Review

Existing literature on travel time estimation focus mainly on two aspects: freeway travel time estimation and arterial travel time estimation. Due to the interrupted natures of traffic flow on urban streets, arterial travel time estimation is more challenging.

Zhang (1997) summarized the early arterial travel time estimation models. He divided them into five different categories:

Regression-type link travel time models

Regression-type models consider whether the travel time is linearly or nonlinearly related to other traffic parameters such as traffic demand, link capacity, and signal timing. Detector occupancy, signal delay and volume are considered to be closely related to travel time in these models (Gault, 1981; Young, 1988).

Dynamic input-output link travel time models

Dynamic input-output models estimate travel time based on time series methods and traffic data, and they can be used to estimate both link and route travel times. Basically, it is based on the traffic flow measure at two locations (Strobel, 1977). Compared to the regression-type models, dynamic input-output models require fewer site-specific parameters and therefore can be applied to broader circumstances.

Sandglass link travel time models

Usami *et al.* (1986) first proposed this model for an oversaturated link. These models divide travel time into two parts: free flow travel time and congested travel time. Free flow travel time is calculated using a constant speed; for congested sections, travel times are the deterministic queuing delays which are related to link length, traffic volume and signal timing. Many later researchers have used similar ideas to develop their own travel time estimation approaches.

As an expansion of the Sandglass type of model, Skabardonis and Geroliminis (2006) further divided the total delay caused by signalized intersections into three categories: a) the delay of a single vehicle approaching a signalized intersection without any interaction with other vehicles, b) the delay because of the queues formed at the intersection, and c) the oversaturation delay. This paper also discussed some extreme situations such as long queues which extended over the detector and queue spillovers when queue from the downstream signal blocked the outflow from the upstream intersection stop line.

Link travel time estimation based on pattern matching

This approach (Bohnke and Pfannerstill, 1986) requires that each vehicle generates a unique signature on an inductive loop detector when passing through its detection zone. Then the sequence of such signatures extracted from an upstream detector is compared with successive sequences of signatures extracted from a downstream detector to find two sequences with the most matches. The time difference between the two sequences is the average travel time.

BPR – Type model

The BPR function (Bureau of Public Roads, 1964) is widely used in estimating link travel time in planning models, especially in traffic assignment. It consists of free-flow travel time and demand-dependent delay:

$$t = t_0 (1 + \alpha (\frac{q}{c})^{\beta}) \tag{1.1}$$

```
Where,
```

```
t is link travel time,

t_0 is free flow travel time,

q is link flow,

c is link capacity; and

\alpha and \beta are two parameters (in practice use, \alpha=0.15 and \beta=4)
```

The Highway Capacity Manual (HCM, 2000) also provided a similar approach to calculate signal delays. However, these models tend to produce unreliable estimation under oversaturation conditions (TRB, 1994).

Zhang (1999) derived the arterial travel time from journey speed. He analyzed a real-world data and concluded that critical V/C ratio, loop detector occupancy, and green band width were the main factors that affect average-link journey speeds.

Probe vehicles are also used widely in travel time estimation. Dailey and Cathey (2002) used a mass transit system as a speed sensor. This approach requires a "transit database" which contains the schedule times and geographical layout of every route and time point. In addition, all the transit vehicles used as probes should be equipped with a transmitter such as GPS receiver, and report back to control center periodically. Liu and Ma (2009) proposed a virtual probe vehicle method for arterial travel time estimation. A virtual probe is a simulated vehicle that is released from the origin to the destination at certain time point. The behavior of the virtual vehicle depends on its position and speed, the current signal status, and queue length ahead. The vehicle could accelerate, decelerate or maintain its original speed from one time step to the next. This approach is used for congested arterials, and the author also claimed that the travel time estimation errors can be self-corrected in their model because the trajectory differences between a virtual vehicle and real one can be reduced when both vehicles meet at a red signal phase and/or a vehicle queue. Recently Hainen et al. (2011) tried to use Bluetooth equipped vehicles as probes to acquire individual travel times. The probe vehicles were required to install Bluetooth devices. When they came through an upstream/downstream detection point, the MAC address of the Bluetooth device was recorded. The travel times were then acquired by matching the MAC addresses.

Herrera et al. (2010) collected data from GPS-enabled Nokia N95 phones to estimate travel time. They claimed that a 2-3% penetration of cell phones in the driver population was enough to provide accurate measurement. In the following research, they extracted travel time distributions from raw GPS measurements and presented the arterial network by a probabilistic model with expectation maximization (EM) algorithm for learning the parameters. (Hunter et al., 2009) One limitation of their work was that they assumed the link travel times were independent. In reality, there are strong correlations between links. Later, Herring et al. (2010) presented two algorithms that based on logistic regression and Spatio-Temporal Auto Regressive Moving Average (STARMA) to forecast short-term traffic conditions by the level of service in an urban network.

However, they only divided traffic conditions into congestion and not congestion and they didn't consider the impact of different signal controls on travel times. In addition, they could only forecast travel times segment by segment. Their model couldn't be able to estimate route travel time.

Statistical modeling, such as Markov Chain and Bayesian models, has also been used in estimating travel time. There are some applications of Markov chain in travel time estimation on freeways and travel time reliability. Yeon et.al (2008) proposed a model based on discrete time Markov chains to estimate travel time on a freeway. They simply divided the system states into 0 (uncongested) and 1 (congested). The travel time of one route was the summation of each link's travel time at different states. They believed the transition matrix would converge to a steady-state no matter what the initial state was. Consequently, a uniform transition matrix was used in their study. Dong and Mahmassani (2009) studied a similar case from a different perspective. They focused on the probabilities of flow breakdown on freeways at peak hour. Lin et.al (2003) proposed a method to estimate travel time on arterials, using a Markov chain model. Similar to previous work, they reduced the continuous delay experienced by drivers at each intersection into two distinctive states: zero-delay and a state of nominal delay. The parameters of the transition matrix of their Markov process was the flow condition at the intersection, the proportion of net inflows into the arterial from the cross streets, and the signal coordination level. A cell transmission model (CTM) was used in the paper to validate the model.

Jintanakul et al. (2009) proposed the use of Bayesian mixture models in estimating freeway travel time. They assumed that travel time came from either a faster component (uncongested conditions) or a slower component (congestion) and tried to use a mixture normal distribution to approximate the travel time probability density. They established a hierarchical Bayesian mixture model to estimate the parameters. They assumed the variances of the normal distributions to be constants to simplify the problem. However, in most real-world cases, variances change under different traffic conditions. This model does not apply to arterial travel time estimation.

1.4 Context of Study

The objective of this report is to develop and test methods utilizing data collected from GPS probe vehicles to characterize arterial travel time. There are two major research interests.

Trip travel time estimation

Given the origin and destination of a trip, how to estimate the total travel time is very attractive to both transportation engineers and general road users. The trip travel time is related to many factors. For example, different routes result in different travel times. For a specific route, travel times under different traffic conditions are different as well. Note that one route usually consists of multiply arterial links. In order to estimate the route travel time, we need to find the patterns of travel times of each arterial link under different traffic conditions first. Furthermore, when signal coordination is in effect, the travel time of each link is not independent. The relationship among individual links need to be captured.

Real-time traffic condition identification

Traffic conditions change throughout a day because of the different signal controls and traffic volume. In order to estimate the trip travel time, we need to know the operating traffic condition. The foundation of distinguishing different traffic conditions is again to characterize the travel times of individual arterial links from historical data. In addition, travel times collected from GPS probe vehicles are also needed to provide real-time information. Finally, the operating traffic condition could be identified by combining the historical travel time patterns and the real-time GPS travel time.

To find the answers to these problems, we need to characterize the travel times of single arterial links and collect real-time GPS data. One way to describe arterial travel time precisely and accurately is to use probability distributions. Travel time distributions could provide many measurements including mean travel time, and standard deviation. The travel time distributions should be estimated as a function of the geometry, the signal settings and the level of congestion to represent different traffic conditions. The real-time GPS data, which reflects the current traffic condition, are then used to refine the corresponding travel time distributions in a learning procedure. As more GPS data sets become available, the travel time distributions will provide updated and more accurate measurements. It is also important to note that GPS data sets are collected under different traffic conditions. Before utilizing these data to update the travel time distributions, they need to be assigned to the right cluster.

1.5 Report Organization

This report focuses on the characterization of arterial travel times by estimating the travel time distribution and GPS data from probe vehicles to predict travel times. Two major themes are addressed by this report:

- 1. Travel time characterization and travel time distribution estimation. Empirical travel time distributions tend to be multi-modal, and can be modeled using mixture distributions. Two approaches are proposed to estimate link travel time distribution with or without prior data.
- 2. After constructing a set of travel time distributions, GPS probe data can be used to identify the correct distribution, estimate the mean route travel time, and the real-time traffic condition. The parameters of travel time distribution can also be updated using a Bayesian model.

The rest of the report is organized as follows: Chapter 2 first introduces the data used throughout the report, and then describes the travel time patterns on signalized arterial links. Chapter 3 introduces two approaches to estimate travel time distributions. Chapter 4 extends individual links to routes, which are defined as sequences of consecutive links, and proposes a model for estimating mean route travel time. In Chapter 5, two applications that combine travel time distributions with GPS data are illustrated. Chapter 6 and Chapter 7 provide two comprehensive case studies using the NGSIM Peachtree Street dataset and Washington Avenue GPS and simulation data. Chapter 8 concludes this report and lays out the directions for further research.

Chapter 2 Characterization of Travel Time Patterns

2.1 Data Introduction

The NGSIM Peachtree Street dataset is used intensively throughout this work. The NGSIM program, led by Federal Highway Administration, is aimed at developing a core of useful and open behavioral algorithms, which improve the quality, and performance of microscopic simulation tools (NGSIM Community, 2011). As part of this program, detailed traffic data were collected on a segment of Peachtree Street, in Atlanta Georgia, on November 8th, 2006. (Cambridge Systematics, 2007) This arterial section is approximately 2,100 feet in length, with five intersections and two to three through lanes in each direction. The section is divided into six links, numbered from one to six running from south to north, divided by the neighboring intersections. Links 1 and 6 turned out to be too short for useful analysis, so our study area is only limited to links 2 through 5. Four of the five intersections are signalized, with intersection 4 being un-signalized. Figure 2.1 shows the geometric structure of the study area. The Peachtree Street data consisted of two 15-minute time periods, 12:45 p.m. to 1:00 p.m. and 4:00 p.m. to 4:15 p.m. These two periods were taken to represent two different traffic conditions, which we call Noon and PM. The data consisted of detailed individual vehicle trajectories with time and location stamps, from which the link travel times of individual vehicles could be calculated. In this study, link travel time refers to the time point a vehicle enters the arterial link to the time point this vehicle passes the stop-bar at the end of the link. Intersection travel time is excluded.

2.2 Characterization of Travel Time

Travel time patterns on signalized arterial links can vary in complexity under different situations. The main factors that affect travel time patterns on an arterial roughly fall into the following four categories:

- Geometric structure of the arterial including link length, number of lanes, speed limit, roadway alignment, and driveways.
- Driving behaviors including lane changing rate, car following behavior and driver aggressiveness.
- Signal control strategy including cycle length, phase splits, effective green time and offsets.
- Traffic demand such as traffic volume of the main arterial, the turning movement flows at the intersections, and the volume ratio between main arterial and the side street.

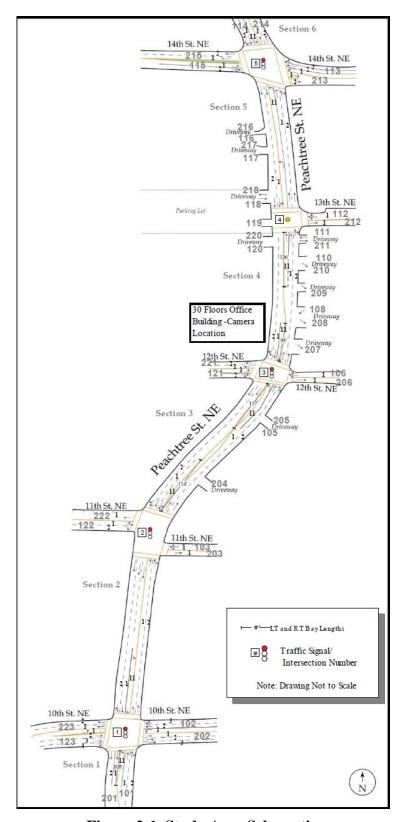

Figure 2-1 Study Area Schematic

Source: NGSIM Peachtree Street (Atlanta) Data Analysis Report (4:00 p.m. to 4:15 p.m.)

For a given location, over the course of the day it is reasonable to think that the geometric structure of the arterial is unchanged and the driving behavior remains similar, leaving the traffic demand and signal control as the determinants of travel time distributions. That is, under a specific traffic condition (combination of signal control strategy and given traffic demand level), it is believed that the travel time distributions are similar. As a result, a set of different travel time distributions are needed for different combinations of demand and signal timing.

Figure 2.2 (a) shows a typical travel time histogram for a signalized arterial link from the NGSIM Peachtree Street dataset (Link 2 Northbound at Noon). This histogram shows the travel time of vehicles that go through to the downstream link. Different colors in the figure represent the different origins of the vehicles. For example, green vehicles come from the through direction of the upstream intersection while brown and grey vehicles come from the side streets of the upstream intersection. Refer to Appendix A to see the list of colors and corresponding origins. It can be seen that travel times of green vehicles cluster around 10 seconds and 70 seconds, and that travel times of grey and brown vehicles tend to fall between those of green vehicles. Apparently, travel times from different origins are different due to different encounters with the different phases of signal control.

Restricting attention to through-through vehicles, defined as vehicles traveling through from the upstream boundary to the downstream, as shown in Figure 2.2 (b), gives a clear two-peak pattern as well as several additional travel time points located between the two peaks or beyond the second peak. The two peaks are the major components of travel time, representing non-stopped vehicles and stopped vehicles. Non-stopped vehicles refer to vehicles that pass the end of the link without stopping, whereas stopped vehicles refer to vehicles stopping at the end of the link for a red phase. The scattered points between the two peaks or beyond the second can be recognized as two additional components: non-stopped with delay and stopped with delay, where the additional delay is not caused by the signal control, but by some other eventuality. For example, a preceding vehicle making a permitted right turn or left turn can delay some through vehicles. Other reasons such as slow moving vehicles, violating the traffic rule, or vehicles entering or exiting from driveways can also cause such delays. All link travel time diagrams for two traffic conditions, Noon and PM, of the NGSIM Peachtree dataset are listed in Appendix A.

In this report, we will restrict attention to through-through vehicles and use the phrase travel time states to represent different travel time components. In short, four states of travel time are defined:

State 1: non-stopped,

State 2: non-stopped with delay,

State 3: stopped,

State 4: stopped with delay

Vehicles that make turns at the end of the intersection or vehicles from minor streets may have different states. The travel time patterns involving turning vehicles are therefore much more complicated than through-through vehicles. For right turning vehicles, usually right turn can be made when the signal is red and sometimes there is no separate right turn bay. For left turning vehicles, similar geometry issues may apply and sometimes the left turn signal is divided into

protected and permitted intervals. Both left turning and right turning vehicles are required to yield to through traffic. Those complexities make it much more difficult to analyze the travel time patterns of turning vehicles. Moreover, through-through vehicles are usually the main component of the total traffic. Therefore, for simplicity, in this report, only through-through vehicles are taken into consideration.

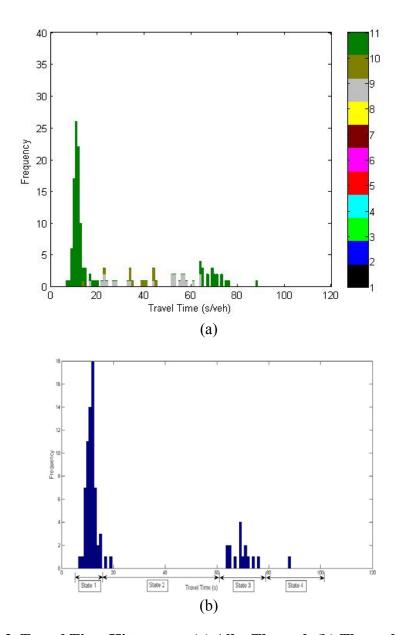

Figure 2-2 Travel Time Histograms (a) All – Through (b) Through – Through

Chapter 3 Estimation of Link Travel Time Distribution

3.1 Estimation with EM Algorithm

Chapter 2 stated that the travel time histogram for through-through vehicle follows a two-peak pattern. Therefore, a bimodal distribution could be used to fit the travel time histogram. Empirical characterization of travel time distributions on signalized arterials shows that this bimodal distribution can be approximated using a mixture of normal densities (Davis and Xiong, 2007; Xiong and Davis, 2009). Maximum likelihood estimates of mixture model parameters can be accomplished using the expectation-maximization (EM) algorithm (McLachlan & Krishnan, 1997). The EM algorithm is briefly introduced here.

Let f(TT) be the probability density function (pdf) of a mixture normal distribution:

$$f(TT) = p \times f_n(TT) + (1-p) \times f_s(TT)$$
(3.1)

Where,

p is the portion of non-stopped vehicles,

 $f_n(TT)$ is the pdf of non-stopped vehicles (first peak), $f_n(TT) \sim N(\mu_1, \sigma_1^2)$ which follows a normal distribution with mean μ_1 and variance σ_1^2 ; and

 $f_s(TT)$ is the pdf of stopped vehicles (second peak), $f_s(TT) \sim N(\mu_2, \sigma_2^2)$ which follows a normal distribution with mean μ_2 and variance σ_2^2

Given the travel time of a specific vehicle, it is unknown whether it belongs to non-stopped vehicles or stopped vehicles. The travel times are then grouped into m intervals, where $m = round(TT_{max} - TT_{min}) + 1$. Consequently, the width of each interval is 1 second. Assume $n_1...n_m$ are the number of travel times that falls into intervals $[a_0, a_1], ..., [a_{m-1}, a_m]$.

Let ψ denotes the parameter set $(p, \mu_1, \sigma_1^2, \mu_2, \sigma_2^2)$. Then the probability that an individual vehicle travel time falls in the j^{th} interval is given by:

$$P_{j}(\psi) = \int_{a_{j-1}}^{a_{j}} f(TT|\psi) dTT, j = 1, ..., m$$
(3.2)

The grouped data then follow a multinomial distribution with likelihood function

$$L(\psi) = \frac{n!}{n_1! \dots n_m!} \{P_1(\psi)\}^{n_1} \dots \{P_m(\psi)\}^{n_m}$$
(3.3)

and the log-likelihood function is

$$\log L(\psi) = \sum_{j=1}^{m} n_{j} \log(P_{j}(\psi)) + \log(\frac{n!}{n_{1}! \dots n_{m}!})$$
(3.4)

Maximum likelihood estimation can now be used to compute the estimates. This method was accomplished using the R software package mixdist (Du, 2002). This routine uses the standard

maximum likelihood estimation method and combines the expectation maximization (EM) algorithm with a Newton-type. (Venables, 2005) Figure 3.1 and Figure 3.2 show the estimated travel time distributions (normal mixture) of state 1 and state 3 of links 2 to 5 under two traffic conditions Noon and PM of the NGSIM Peachtree Street dataset. As mentioned above, intersection 4 is an un-signalized intersection, and left turns at intersection 4 were forbidden, so link 4 and link 5 were treated as one single link, yielding three consecutive links. Note that all travel time distributions in Figure 3.1 and Figure 3.2 show that the traffic conditions are not oversaturated. Under oversaturated traffic conditions, the distribution may have a third peak representing vehicles in the residual queue (stopped twice). The EM algorithm could be applied to oversaturated traffic conditions where the travel time distributions have more than two components.

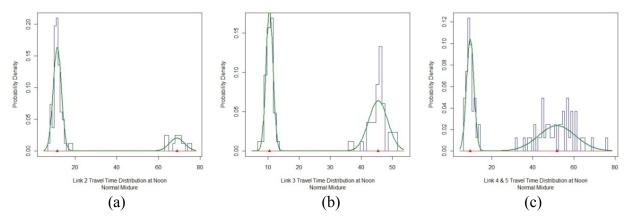

Figure 3-1 Normal Mixture Approximation of Travel Time State 1 & 3 at Noon

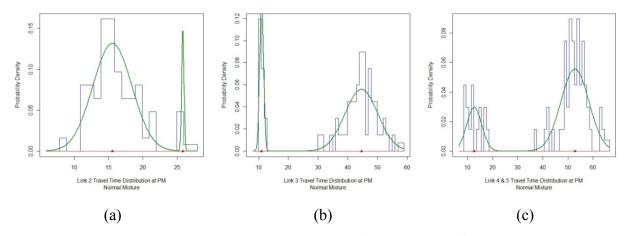

Figure 3-2 Normal Mixture Approximation of Travel Time State 1 and 3 at PM

The mixture distributions in Figure 3.1 and Figure 3.2 only represent stopped and non-stopped components, which are vehicles in state 1 and state 3. Since the number of observations in state 2 and state 4 is very small, it is difficult to identify a unimodal distribution for these. So it is assumed that the probabilities of delay times caused by different 'incidents' in state 2 and state 4 are equally likely, which indicates travel times in state 2 or state 4 follow uniform distributions.

The upper boundary and lower boundary of these two uniform distributions can be defined as follows. Suppose the non-stopped component is normally distributed with mean and variance μ_1 and σ_1^2 while the stopped component is normal with mean and variance μ_2 and σ_2^2 . If an observed travel time is located beyond $\mu_1 + 3\sigma_1$ which is approximately the 99th percentile for the state 1, then it is reasonable to think that this travel time does not belong to state 1, and $\mu_1 + 3\sigma_1$ is considered as the lower boundary of the uniform distribution for state 2 (non-stopped with delay). Based on this rule, the upper boundary for non-stopped with delay, and the lower boundary for stopped with delay can be defined. The upper boundary for state 4 (stopped with delay) is assumed not to exceed a certain value TT_{max} , which is the longest possible travel time in one arterial link.

3.2 Prior Estimation Based on Signal Control and Geometry

The previous section described how to estimate a travel time distribution based on individual vehicle travel times. However, under many circumstances, travel times of individual vehicles are not readily available. As an alternative, this section proposes an approach to compute prior of travel time distributions for state 1 and state 3 based on the signal control and geometric structure of the arterial link.

Some assumptions are made to simplify the problem. First, the signals of upstream and downstream intersections are coordinated, which means that the signals should have the same cycle length. Second, queues can be fully discharged during one cycle so that non-oversaturated traffic condition applies. Third, the turning rate from side streets is negligible. This assumption assures that vehicles from side streets should not affect the travel time on the main arterial too much.

Given the assumption that the travel time distribution for state 1 and state 3 can be approximated using mixture of normal densities as shown in Equation 3.1, five parameters $(\mu_1, \sigma_1^2, \mu_2, \sigma_2^2, p)$ need to be estimated.

Estimation of μ_1

 μ_1 is the mean travel time of non-stopped vehicles, which can be considered as free flow travel time. It could be estimated by section length and speed limit:

$$\mu_l = L/V_L \tag{3.5}$$

Where,

L is the section length; and

 V_L is the speed limit of the arterial link.

Estimation of σ_1

 σ_I is the standard deviation of the free flow travel time. Unfortunately, there is no direct way to estimate the standard deviation of travel time without data. However, since travel time is the reciprocal of speed given a section length, σ_I can be converted from the standard deviation of

speed. Empirical studies suggest that standard deviation of speed varies a lot under different demands. For example, it shows a U-shape (Nezamuddin *et al.*, 2009) relation with respect to traffic volume. That is, when either the traffic demand is low or high, the standard deviation increases. When the traffic demand is within intermediate ranges, the standard deviation remains low and stable. Existing literatures (Box and Oppenlander, 1976; Oppenlander, 1963) suggest a standard deviation of 5-7 mph for speed distribution under intermediate range of demand.

Estimation of μ_2 σ_2

 μ_2 and σ_2 are mean travel time and standard deviation of stopped vehicles, which are closely related to the signal settings of the upstream and downstream intersections.

By assumption, the travel time of stopped vehicles also follows a normal distribution. According to the properties of normal distribution, if one wants to estimate the mean and standard deviation, instead of estimating directly, they could estimate the lower and upper boundary of 99^{th} percentile first and calculate the mean and standard deviation accordingly. Figure 3.3 shows the probability density function (pdf) of a normal distribution. Suppose the lower and upper boundary of the 99^{th} percentile are a and b respectively. Then by the symmetry property, the mean could be calculated as $\mu = (a+b)/2$. Moreover, the distance from the mean to the 99^{th} percentile is 3σ . Therefore, standard deviation could be calculated as $\sigma = (b-\mu)/3$ or $\sigma = (\mu-a)/3$.

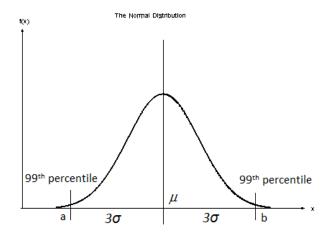

Figure 3-3 Normal Distribution pdf

Now the key question is how to estimate the upper and lower boundary of the 99th percentile of link travel time. It can be estimated by adding the upper and lower boundary of signal delay to free flow travel time.

To estimate upper and lower boundary of signal delay, we need to know the signal control plan such as cycle length, green and red split and the offset between upstream and downstream intersections. An example time-space diagram of two consecutive intersections is shown in Figure 3.4. The arrow on the right is the movement direction.

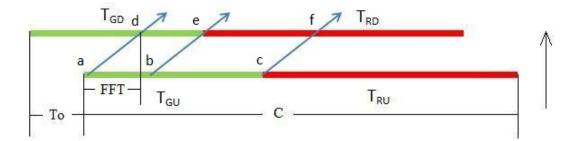

Figure 3-4 Time-Space Diagram for Two Consecutive Intersections

Where,

 T_{GD} and T_{RD} are the green/red time of downstream intersection

 T_{GU} and T_{RU} are the green/red time of upstream intersection

C is the cycle length

To is the offset between two signals

FFT is the non-stopped vehicle mean travel time (equals to μ_l)

By looking at the time-space diagram, one can easily see that vehicles pass during T_{GD} are non-stopped vehicles while vehicles reach the downstream intersection during T_{GD} are stopped vehicles. The estimation of the upper and lower boundaries of signal delay can be categorized into the follow three cases:

Case I
$$To + \mu_I < T_{GD} < To + T_{GU} + \mu_I$$

$$D_{upper} = T_{RD} \qquad D_{lower} = C - (To + T_{GU} + \mu_I)$$
Case II $T_{GD} < To + \mu_I$

$$D_{upper} = C - (To + \mu_I)$$
if $To + T_{GU} + \mu_I < C \rightarrow D_{lower} = C - (To + T_{GU} + \mu_I)$
if $To + T_{GU} + \mu_I > C \rightarrow D_{lower} = 0$
Case III $T_{GD} > To + T_{GU} + \mu_I$

$$D_{upper} = 0 \qquad D_{lower} = 0$$

Where,

 D_{upper} and D_{lower} are upper and lower boundaries of signal delay

In case I, where $T_0 + \mu_l < T_{GD} < T_0 + T_{GU} + \mu_l$, the start of the green at the downstream intersection is between the green time start of the upstream intersection plus the free flow travel time, and the green time end of upstream intersection plus free flow travel time. That is, point e is between point a and point c in Figure 3.4. Suppose vehicle 1 passes upstream intersection at point b and arrives downstream intersection at the beginning of the red signal (point e). Since there is no residual queue from the previous cycle, vehicle 1 must be the first in the queue and thus would not experience extra queue discharging time. Then the longest signal delay time is considered the duration of red signal at downstream intersection. Suppose vehicle 2 passes the upstream intersection at time point c and arrives downstream intersection at time point f. Its signal delay time is from time point f until the end of red signal at downstream intersection. Only if no vehicle passes the upstream intersection between time point b and c, would vehicle 2 be the only vehicle in the queue. Otherwise, vehicle 2 would experience extra queue discharging delay. So the shortest delay time is considered as the length of the red time from the time point when vehicles, which passed the upstream intersection at the end of the green time, arrive the downstream intersection to the end of red signal (from point f to the end of G_{RD}). Case II and Case III are analyzed in a similar way.

Therefore the lower and upper boundary of 99th percentile of travel time could be approximated as:

$$TT_{upper} = D_{upper} + \mu_I + 3\sigma_I + T_R$$
(3.6)

$$TT_{lower} = D_{lower} + \mu_1 - 3\sigma_1 + T_R$$
(3.7)

Where,

TT_{upper} and TT_{lower} are the upper and lower boundary of travel time respectively; and

T_R is the start delay.

From Figure 3.3, $\mu_I + 3\sigma_I$ is the upper boundary of 99th percentile of non-stopped vehicle (free flow) travel times and travel time of stopped vehicles could be treated as free flow travel time plus signal delay. Therefore, TT_{upper} could also be considered as the upper boundary of 99th percentile of travel time for the stopped vehicles. For the same reason, TT_{lower} is the lower boundary of 99th percentile of travel time.

Then, μ_2 and σ_2 can be calculated as:

$$\mu_2 = (TT_{upper} + TT_{lower})/2 \tag{3.8}$$

$$\sigma_2 = (\mu_2 - TT_{lower})/3$$
 or $\sigma_2 = (TT_{upper} - \mu_2)/3$ (3.9)

Estimation of p

Since the parameter p is the proportion of non-stopped vehicles and 1-p is the proportion of stopped vehicles, it can be estimated by combining the signal timing information and arrival rate at the entrance of the corridor, as shown in Figure 3-5.

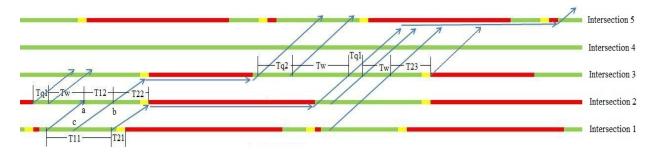

Figure 3-5 Example on Estimation of *p*

Suppose Intersection 1 is the entrance of the corridor. Based on the time-space diagram and the free flow speed, (shown as the slope of the arrows in the figure) vehicles passing Intersection 1 during T_{11} are non-stopped vehicles while vehicles pass during T_{21} are stopped vehicles. Let the average arrival rates (veh/s) during T_{11} and T_{21} be q_1 and q_2 respectively. The average arrival rate could be obtained for example from loop detectors at the stop bar. Therefore the number of non-stopped vehicles on the link between Intersection 1 and Intersection 2, $N_{11}=T_{11}\times q_1$, and the number of stopped vehicles $N_{21}=T_{21}\times q_2$. Then ratio of the first link $p_1=N_{11}/(N_{11}+N_{21})$.

The situation gets more complicated when calculating the ratio for the second link. The vehicles passing during T_{21} become a queue at Intersection 2. When the signal turns green at Intersection 2, it takes time T_{q1} to discharge the queue, which is propagated during T_{21} . As a result, stopped vehicles in link 1 become non-stopped vehicles in link 2. After the queue is fully discharged, there is a period of time T_w when no vehicles pass Intersection 2 because the next platoon from intersection 1 will not arrive at Intersection 2 until time point a. So vehicles which pass Intersection 2 between point a and point b (T_{12}) are non-stopped vehicles while vehicles passing Intersection 2 between point b and the green time end (T_{22}) are stopped vehicles. The total number of non-stopped vehicles in link 2, say, N_{12} is equal to number of vehicles passing during T_{q1} and T_{12} . So $N_{12} = N_{21} + T_{12} \times_{q1}$. The number of stopped vehicles of links $N_{22} = T_{22} \times q_1$. Then ratio of non-stopped vehicles at link 2, $p_2 = N_{12}/(N_{12} + N_{22})$. The subsequent links are analyzed in a similar way.

Different signal settings and different offsets will result in different scenarios. For example, there are two periods of unused green time T_w at intersection 3. However, the analysis technique is the same and can be applied to most real world situations.

Figure 3.6 shows a comparison of travel time distributions estimated from signal timing and geometry (red curve) and from data using EM algorithm (blue curve). The NGSIM Peachtree Street Dataset noon traffic condition was used for the test. Although the estimation of some parameters, such as the mean of the second peak in Section 3, is not very accurate, they are good enough for a prior distribution for further updating. A detailed description of how to update travel time distributions will be given in Chapter 5.

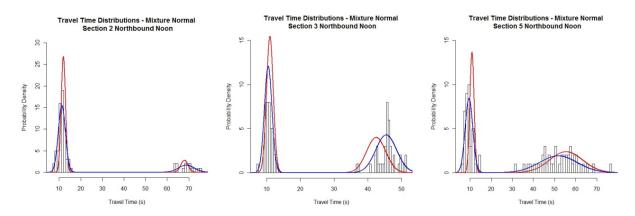

Figure 3-6 Comparison, EM Algorithm and Estimation from Signal Timing and Geometry

Chapter 4 Estimation of Mean Route Travel Time

So far the discussion of travel time estimation has been limited to a single arterial link. However, it is more useful if the route travel time can be estimated. A route is defined as a consecutive sequence of arterial links. General road users are more interested in obtaining the travel time information from their origins to destinations, which most likely consists of multiple links. This chapter proposes a method based on Markov Chains to estimate mean route travel time.

Due to the signal control, congestion, and traffic from the side street, a vehicle's travel times between arterial links is not necessarily independent. For example, vehicles that did not stop on an upstream link may have a certain probability of not stopping on the downstream link while vehicles that were stopped on the upstream intersection could have a different probability of not stopping on the downstream link. The simplest case would be that the travel time on the current link depends only on the state encountered on the immediate upstream link. More succinctly, the sequence of traffic states encountered on the arterial links is governed by a Markov Chain (Anderson and Goodman, 1957; Lin et al., 2003; Geroliminis and Skabardonis, 2005). For example, the transition matrix for two consecutive links, with two traffic states is:

$$P_k = \begin{bmatrix} p_{11,k} & 1 - p_{11,k} \\ 1 - p_{00,k} & p_{00,k} \end{bmatrix}$$

Where,

 $p_{11,k}$ is the probability of a non-stopped travel time state on link k given non-stopped travel time state on link k-; and

 $p_{00,k}$ is the probability of stopped travel time state on link k given stopped travel time state on link k-1

To use a Markov Chain to describe the movement through a sequence of arterial links, the system states, the transition matrix, and initial state probabilities should be defined properly.

System States: System states are different travel time categories that can be derived from link travel time distribution diagrams. Suppose our interest is focused on through – through vehicles. As stated in Section 2.1 and illustrated in Figure 2.2 (b), four states in the system are defined: non-stopped, non-stopped with delay, stopped, and stopped with delay.

Transition matrix: Four system states results in a four by four transition matrix. The one step transition matrix (two consecutive links) is shown as the following matrix, where p_{ij} indicates the probability of switching from travel time state i to j.

$$P = \begin{pmatrix} p_{11} & p_{12} & \cdots & p_{14} \\ p_{21} & p_{22} & \cdots & p_{24} \\ \vdots & \vdots & & \vdots \\ p_{41} & p_{42} & \cdots & p_{44} \end{pmatrix}$$

 p_{ij} also could be expressed in conditional probability as follows:

$$p_{ij} = P\{S_{n+1} = j | S_n = i\} \quad \text{for i, j = 1,2, ..., 4 and n = 1,2,3, ...} \tag{4.1}$$

Where,

 $S_{n+1} = j$ indicates travel time state at link n+1 is j.

Initial State Probabilities: Initial state probabilities are defined as the probabilities of each travel time state before vehicles entering the first link of the route.

$$\lambda_0 = (\lambda_{01} \quad \lambda_{02} \quad \lambda_{03} \quad \lambda_{04})$$

Where,

 λ_0 is the initial state probability vector which is consistent with the travel time states and $\sum_{i=0}^4 \lambda_{0i} = 1$.

The Markovian property can also be expressed as conditional probability as follows:

$$P\left\{S_{n+1} = j \middle| S_n = i, S_{n-1} = i_{n-1}, S_{n-1} = i_{n-2} \cdots S_1 = i_1\right\} = P\left\{S_{n+1} = j \middle| S_n = i\right\} = p_{ij}$$
 (4.2)

Because of the conditional independence, the joint probability of each step in a Markov Chain is the product of the transition probabilities of each step:

$$P\{S_0 = i_0, S_1 = i_1 \cdots, S_n = i_n\} = \lambda_{0i} p_{i_0 i_1} p_{i_1 i_2} \cdots p_{i_{n-1} i_n}$$

$$(4.3)$$

Based on Equation 4.3, given the initial distribution λ_0 and all the link-link transition matrices $P^{(x)}$, the mean route travel time can be calculated by multiplying the mean travel time of each possible combination of system states and its probability. That is:

$$TT_{route} = \sum_{i_1=1}^{4} \sum_{i_2=1}^{4} \cdots \sum_{i_n=1}^{4} \left(T_{i_1}^{(1)} + T_{i_2}^{(2)} + \cdots + T_{i_n}^{(n)} \right) \times p_{i_0 i_1} \times p_{i_1 i_2} \times \cdots \times p_{i_{n-1} i_n}$$
(4.4)

Where,

 TT_{route} is mean route travel time, and $T_{i_k}^{(j)}$ mean travel time of link j is in state i_k .

Theoretically there are total 4^n possible different combinations of travel time states from origin to destination, where n is the total number of link in the route. However, if the traffic signals along the route are coordinated, the signal control will tend to reduce the possible combinations. In addition, the probabilities of travel time state 2 and state 4 may be small, which means that those states might not be observed in a finite sample.

To check on the validity of this model, predicted mean route travel times are compared to the measured route travel time. Travel times of noon traffic condition of NGSIM Peachtree St dataset (Figure 3.1) are used to test the model. To apply Equation 4.4, mean travel times of each state in every link need to be calculated first. These are just the means of corresponding distributions. The result is shown in Table 4.1.

Table 4-1 Estimated Mean Travel Times of Different States in Each Link

	State 1	State 2	State 3	State 4
Link 2	11.29	38.12	68.87	88.08
Link 3	10.49	26.02	45.47	75.82
Link 4	9.54	N/A	N/A	N/A
Link 5	9.58	23.47	51.76	84.88

Theoretically, there are four different initial states. However, in almost all cases, the initial state of travel time is either state 1 (non-stopped) or state 3 (stopped), so the initial probabilities of states 2 and 4 were taken to be zero.

Case I: Given the vehicle is a non-stopped vehicle at the entrance

Initial state: $\lambda_0 = [1 \ 0 \ 0 \ 0]$;

The transition matrices estimated from the data are:

$$P^{(3)} = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 12/13 & 0 & 1/13 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

Where,

 $P^{(1)}$ is the transition matrix from initial distribution to travel time states of Link 2,

P⁽²⁾ is the transition matrix from Link 2 to Link 3,

P⁽³⁾ is the transition matrix from Link 3 to Link 5, since Link 4 only has one state.

Only 4 combinations of travel time state sequence were observed:

The value in the bracket is the probability of this particular travel time states combination.

The estimated mean route travel time is:

$$TT = (11.29+10.49+51.76) \times 0.0370 + (11.29+45.47+9.58) \times 0.4444+$$

$$(11.29+45.47+51.76) \times 0.0370 + (68.87+10.49+51.76) \times 0.4815 + 9.54$$

$$= 108.89s$$

The mean travel time from the data is 110.78s, and an approximate 95% confidence interval is (97.16s; 124.40s).

Case II: Given the vehicle is a stopped vehicle at the entrance

Initial state: $\lambda_0 = [0 \ 0 \ 1 \ 0]$;

The transition matrices estimated from the data are:

$$P^{(1)} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 50/55 & 2/55 & 2/55 & 1/55 \\ 0 & 0 & 0 & 0 \end{bmatrix} P^{(2)} = \begin{bmatrix} 24/50 & 0 & 26/50 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix}$$

$$P^{(3)} = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 25/28 & 0 & 1/28 & 2/28 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

There are 7 combinations of travel time state sequences observed here:

The predicted mean route travel time is:

$$TT = (11.29+10.49+51.76) \times 0.4364 + (11.29+45.47+9.58) \times 0.4182 +$$

$$(11.29+45.47+51.76) \times 0.0182 + (11.29+45.47+84.88) \times 0.0364 +$$

$$(68.87+10.49+51.76) \times 0.0364 + (38.12+45.47+9.58) \times 0.0364 +$$

$$(88.08+10.49+51.76) \times 0.0182 + 9.54$$

$$= 87.40s$$

The mean travel time from the data is 86.25s, with an approximate 95% confidence interval of (79.59s; 92.91s).

It is shown in the results from both cases that estimated mean route travel times from the Markov Chain model are close to those measured from data. That means this Markovian relationship could approximate the dependence of consecutive travel time states.

Chapter 5 Applications of Travel Time Distribution

Travel time distributions provide a range of performance measures, such as mean travel time, the standard deviation, and the 95th percentile travel time. Meanwhile, GPS data offer information of individual vehicle information in real-time. Useful information can be derived combining travel time distribution and GPS data. This Chapter describes how real-time traffic conditions can be identified, and how to update the parameters of travel time distribution.

5.1 Real-Time Traffic Condition Identification

Figure 3.1 and Figure 3.2 show that the travel time distributions of each link under different traffic conditions are different. In consequence, transition matrices between links may also be different. Therefore, different traffic conditions should be characterized by travel time distributions of each link, in each state, and the sequence of link-link transition matrices. When a GPS probe vehicle goes through a certain route, it records travel time of each individual link. The probabilities that this travel time sequence belongs to each existing traffic condition are also different. If the probability that this travel time sequence belongs to traffic condition A is higher than all other traffic conditions, it possibly suggests that the current traffic condition is A. Then how to calculate these posterior probabilities becomes a key question. One approach using Bayes Theorem is proposed next.

Either the travel time distribution of the whole route or the travel time distribution of each link can be used to identify a traffic condition. Using the travel time of the whole route is a more direct way. However, it is more feasible to use travel time distribution of every single link because then the route could be constructed freely as long as the relationship between links can be found. In addition, under different traffic conditions, the travel time distribution of the whole route could be similar, even though the travel time distributions of single links differ. Therefore, in this study, link travel time distributions are used.

Suppose an arterial route consists of n consecutive links, and a sequence of travel time data of each link is collected from a GPS vehicle running along this route. Let S_i and T_i denote travel time state and travel time of link i respectively. The joint probability of travel time states could be expressed by the following equation.

$$P(S_{1} = s_{1}, S_{2} = s_{2}, ..., S_{n} = s_{n}) = P(S_{n} = s_{n} | S_{n-1} = s_{n-1}, ..., S_{2} = s_{2}, S_{1} = s_{1}) \times P(S_{n-1} = s_{n-1} | S_{n-2} = s_{n-2}, ..., S_{2} = s_{2}, S_{1} = s_{1}) \times ... \times P(S_{2} = s_{2} | S_{1} = s_{1}) \times P(S_{1} = s_{1})$$

$$= s_{1}$$

$$(5.1)$$

Assuming the travel time of a single link is conditionally independent of travel time states on other links:

$$P(T_i = t_i | S_1 = s_1, S_2 = s_2, ..., S_i = s_i, ..., S_n = s_n) = P(T_i = t_i | S_i = s_i)$$
(5.2)

Combined with Equation 5.1 and Equation 5.2, the joint distribution of travel time and travel time states can be seen in Equation 5.3.

$$P(T_1 = t_1, ..., T_n = t_n, S_1 = s_1, ..., S_n = s_n) = \left(\prod_{i=1}^n P(T_i = t_i | S_i = s_i)\right) P(S_1 = s_1, ..., S_n = s_n)$$
(5.3)

So the marginal distribution for travel times becomes

$$P(T_1 = t_1, ..., T_n = t_n) = \sum_{S_1 = S_1, ..., S_n = S_n} \left(\prod_{i=1}^n P(T_i = t_i | S_i = s_i) \right) P(S_1 = s_1, ..., S_n = s_n)$$
(5.4)

Assuming there are m different traffic conditions, the probability that a given travel time sequence belongs to traffic condition C_i can be calculated by Bayes theorem (DeGroot, and Schervish, 2002)

$$P(C_{i}|T_{1} = t_{1}, ..., T_{n} = t_{n}) = \frac{P(T_{1} = t_{1}, ..., T_{n} = t_{n}|C_{i}) \times P(C_{i})}{\sum_{i=1}^{m} P(T_{1} = t_{1}, ..., T_{n} = t_{n}|C_{i}) \times P(C_{i})}$$
(5.5)

Since the travel time distributions under every traffic condition are known, the likelihood $P(T_1 = t_1, ..., T_n = t_n | C_j)$ can be obtained from Equation 5.4. The prior probability $P(C_j)$ can be flat or calculated from the traffic volume of each traffic condition. For example, in the NGSIM Peachtree St Dataset, there are two traffic conditions: noon and PM. 82 vehicles went through the route during the noon period and 67 vehicles during the PM period. If a vehicle is randomly picked, the probability it belongs to noon data set, which is P(Noon)=82/(82+67)=0.55. Consequently, P(PM)=1-0.55=0.45. Then the marginal distribution of travel time under different traffic conditions $P(T_1 = t_1, T_2 = t_2, T_3 = t_3 | noon)$ and $P(T_1 = t_1, T_2 = t_2, T_3 = t_3 | PM)$ can be then calculated from travel time distributions.

Because currently GPS data of that arterial segment are not available, travel time data from the NGSIM Peachtree St Dataset are used to test the method. If it works well, vehicles from the Noon data set should have a high posterior probability of belonging to the noon traffic condition and a low probability of belonging to the PM traffic condition, and vice versa. Figure 5.1 shows the results.

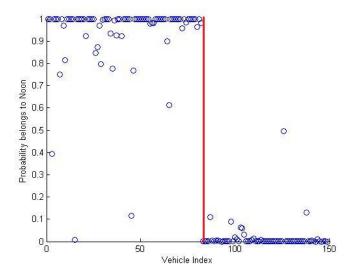

Figure 5-1 Traffic Condition Identification

The dots on the left side of the vertical line in Figure 5.1 are the vehicles from the noon data set and right side are the vehicles from the PM data set. One dot represents one vehicle. The figure shows that generally, data from a single GPS-equipped vehicle could be enough to discriminate between the two traffic conditions. Although the probabilities of a few dots on the left are low, most of them located around one. It is worth pointing out that the identification could be wrong (the other side) or vague (the probability is around 0.5). In that case, more than one GPS vehicle is needed to identify the traffic condition.

5.2 Travel Time Distribution Parameter Update

This section proposes an approach to update the parameters of the travel time distribution under a Bayesian scheme. To apply a Bayesian approach, a prior distribution must be chosen first. When no prior information is available, it is common to use a non-informative prior. A non-informative prior is usually a uniform distribution or a normal distribution with a large variance that has minimal impact on the posterior distribution. Many statisticians are in favor of non-informative priors because they appear to be more objective. But in some cases, non-informative priors can lead to improper posteriors. More importantly, in this case, even if the non-informative prior is a proper prior, given the density of the GPS probe vehicles is very low and spread into different traffic conditions, it might take a very long time to update to a good posterior distribution. Especially under traffic conditions such as off-peak hours when there are fewer GPS probes, the time would be even longer. Consequently, we considered travel time distributions estimated from signal timing and geometric structure of the arterial (Chapter 3.2) as prior distribution when no prior travel time data is available. Combining with GPS data, posterior distributions can then be calculated.

Unfortunately, the posterior distribution of a mixture normal density is analytically intractable (McLachlan and Peel, 2000). As a result, Markov Chain Monte Carlo (MCMC) simulation (Berg, 2004) is applied to estimate the posterior distribution. One particular sampling technique of Markov Chain called Gibbs sampling (Diebolt and Robert, 1994) is used. In this paper,

WINBUGS ("BUGS" stands for Bayesian inference using Gibbs sampling) software is used to compute the posterior distributions.

Notice that the mixture normal distribution consists of two unimodal normal distributions and the two normal components are connected by the ratio p. p follows a Bernoulli random variable, which captures the variations of the portions of the two components. For a unimodal normal distribution with unknown mean and variance, there is conjugate prior for the posterior distribution, given the data are iid normal.

The conjugate prior for a two parameter normal is the normal-inverse gamma distribution (Bernardo and Smith, 1993) with density

$$f(\mu, \sigma^2) = f(\mu | \sigma^2) f(\sigma^2)$$

When $f(\mu|\sigma^2) = N(\alpha_0, \beta_0)$ and $f(\sigma^2) = IG(\gamma_0, \delta_0)$, $IG(\gamma_0, \delta_0)$ is the Inverse-gamma distribution with parameters γ_0, δ_0 . Note that if $X \sim IG(\gamma_0, \delta_0)$, then $X^{-1} \sim Gamma(\gamma_0, \delta_0)$. Therefore, we replace σ^2 with precision $\lambda = 1/\sigma^2$. With this approach, the prior for the parameter (μ, λ) is a normal-gamma distribution, denoted by

$$f(\mu, \lambda) \sim NG(\alpha_0, \beta_0, \gamma_0, \delta_0)$$

Suppose the data (likelihood) are iid normal, $f(Y_i|\mu,\lambda) \sim N(\mu,\lambda)$ i=1,2,...,n. Because of independence, the total likelihood is the product of each likelihood, denoted by $f(Y|\mu,\lambda) = \prod_{i=1}^n f(Y_i|\mu,\lambda)$. Suppose the sample mean is \mathcal{Y} and the sample variance is V_n . Then, the corresponding posterior distribution is also a normal-gamma distribution with parameters $(\alpha_1,\beta_1,\gamma_1,\delta_1)$.

$$f(\mu, \lambda | y) = f(Y | \mu, \lambda) \times f(\mu, \lambda) = NG(\alpha_1, \beta_1, \gamma_1, \delta_1)$$

Where,

$$\alpha_1 = \alpha_0 + \frac{n_1}{2}, \beta_1 = \beta_0 + \frac{n_1}{2} \left(V_n + \frac{\delta_0 (\bar{y} - \gamma_0)^2}{\delta_0 + n_1} \right), \gamma_1 = \frac{\gamma_0 \delta_0 + n_1 \bar{y}}{\delta_0 + n_1}, \delta_1 = \delta_0 + n_1$$

Given the above structure, a hierarchical Bayesian model could be constructed in WINBUGS. The structure of the hierarchical model can be specified as below:

$$Y_i | Pi, \lambda_{(Pi)}, \mu_{(Pi)} \sim Normal(\mu_{(Pi)}, \lambda_{(Pi)})$$

$$\mu_{\,(Pi)}|\;Pi,\,\lambda_{\,(Pi)}\sim Normal\;(\epsilon_{\,(Pi)},\!\delta_{\,(Pi)}\,)$$

$$\lambda_{(Pi)} | Pi \sim Gamma(\alpha_{(Pi)}, \beta_{(Pi)})$$

P_i~ Bern(r) r: determined by ratio of non-stopped and stopped vehicles

Some simulation experiments are run in WINBUGS to test the model. The number of Markov Chains is set to one. One simulation scenario includes 21,000 samples, in which the first 1,000

samples are burn-in samples and the following 20,000 samples are used to create the posterior distribution. The posterior means of each parameter are selected to be the new parameters of the travel time distribution. Figure 5.2 shows an example of the comparison between the posterior travel time distribution from Bayesian update (red curve) and travel time distribution directly estimated from EM algorithm (blue curve). In this example, same travel time data are used. One can see the two approaches lead to similar results because asymptotically Bayesian inference and classical maximum likelihood estimation should converge to the same distribution when the sample size is big enough.

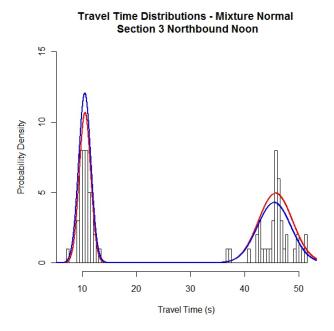

Figure 5-2 Posterior Travel Time Distribution

Chapter 6 A Case Study – NGSIM Peachtree Dataset

In previous chapters, methods regarding for constructing travel time distribution and their applications were discussed. This chapter aims to connect these models together and demonstrate a comprehensive case study based on the NGSIM Peachtree dataset.

Suppose we are interested in estimating the travel time distributions of a given arterial under different traffic conditions. Usually the signal timing plans and the geometric structure of the arterial are known, but the travel time data are not available in the first place. As a result, instead of starting with flat prior, travel time distributions are estimated based on signal timing plans and the geometric structure of the arterial. (Chapter 3.2) When GPS data are collected for the targeted route, traffic condition identification process (Chapter 5.1) is run and the probability one particular data point belongs to every traffic condition is calculated. Data are then classified according to the posterior probabilities. Finally, a Bayesian update (Chapter 5.2) is run to calculate posterior distributions under each traffic condition combining with classified data. Furthermore, when new GPS data are available, the posterior distributions from the previous update are considered as new priors and the update process is repeated. As long as more and more GPS data become available, the posterior distribution would be more and more consistent with reality. Figure 6.1illustrates the process stated above.

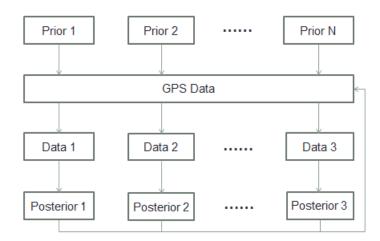

Figure 6-1 Travel Time Distribution Update Process

The NGSIM Peachtree Street dataset are used to test the scenario. There are two traffic conditions in the dataset: Noon and PM. We assume there is no prior travel time data under both traffic conditions and consider travel time data from vehicle trajectories as incoming GPS data. The total sample size of GPS data in two traffic conditions is 149 which are further divided into two parts in order to perform the update process iteratively. One GPS datum is one travel time sequence including the three link travel times in section 2, section 3 and section 5 respectively.

6.1 Prior Distributions

First, prior distributions are estimated from signal timing and geometric structure of the arterial. Table 6.1 and Table 6.2 list the distribution parameters under traffic condition Noon and PM respectively.

Table 6-1 Prior Travel Time Distribution Parameters of Each Section at Noon

	μ_1	σ_1	μ_2	σ_2	p
Section 2	12	1.1	68	1.667	0.852
Section 3	11	1	42.5	2.833	0.577
Section 5	11	1	56.5	7.833	0.423

Table 6-2 Prior Travel Time Distribution Parameters of Each Section at PM

	μ_1	σ_1	μ_2	σ_2	p
Section 2	12	1.1	18	2.33	0.682
Section 3	11	1	43	3	0.343
Section 5	11	1	55.5	6.83	0.324

6.2 Data Classification

The traffic condition identification process is then performed on the first half of the data (75 travel time sequences). Figure 6.2 shows the probabilities that each GPS vehicle belongs to Noon.

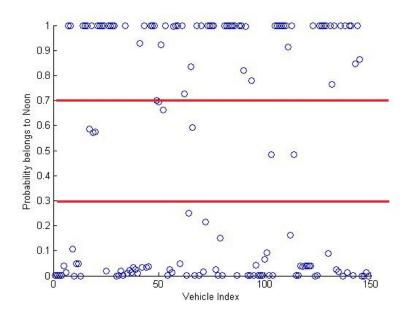

Figure 6-2 Data Classification Based on Prior Distribution

The following criteria are applied while classifying the data:

If P(belong to noon)>=0.7 -> use this data to update Noon travel time distribution

If P(belong to noon)<=0.3 -> use this data to update PM travel time distribution

If 0.3<P(belong to noon)<0.7 -> discard the data (because it is too vague to tell which traffic condition this data belongs to)

6.3 Bayesian Update

Applying the Bayesian update, the posterior means of each parameter under different traffic conditions, after updating with 75 observations are shown in Table 6.3 and Table 6.4.

Table 6-3 Posterior Travel Time Distribution Parameters of Each Section at Noon after Updating Half of Data

	μ_1	σ_1	μ_2	σ_2	p
Section 2	11.87	1.848	70.59	2.821	0.7318
Section 3	10.47	1.108	45.21	3.457	0.4574
Section 5	10.16	1.472	54.59	8.707	0.5248

Table 6-4 Posterior Travel Time Distribution Parameters of Each Section at PM after Updating Half of Data

	μ_1	σ_1	μ_2	σ_2	p
Section 2	13.21	1.371	19.52	2.818	0.6406
Section 3	10.96	1	45.28	4.561	0.2433
Section 5	12.03	1.183	52.54	6.2	0.1478

6.4 Repetition

Considering the posterior distributions in Table 6.3 and Table 6.4 as new prior distributions, the traffic condition identification process is performed again on the second half of the data (74 samples). Figure 6.3 shows the identification result after updating all samples.

The same criteria are applied to classify the data and then the corresponding posterior distributions are updated. Table 6.5 and Table 6.6 show the posterior means of each parameter under different traffic conditions (Noon and PM) after updating with all 149 observations.

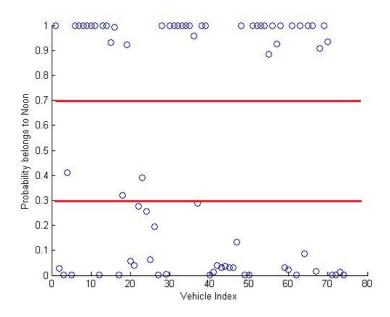

Figure 6-3 Data Classification Based on First Posterior

Table 6-5 Posterior Travel Time Distribution Parameters of Each Section at Noon After Updating All Samples

	μ_1	σ_1	μ_2	σ_2	p
Section 2	10.99	1.408	66.68	2.541	0.8204
Section 3	10.52	0.9083	45.88	2.4368	0.4221
Section 5	9.369	1.6507	52.79	8.4215	0.6021

Table 6-6 Posterior Travel Time Distribution Parameters of Each Section at PM After Updating All Samples

	μ_1	σ_1	μ_2	σ_2	p
Section 2	14.51	1.4767	21.68	3.5132	0.5918
Section 3	11	0.7638	44.14	4.3315	0.2715
Section 5	12.92	2.4884	50.65	7.7452	0.2104

Figure 6.4 and Figure 6.5 show the comparison among prior distributions (yellow), posterior distributions after updating half of the data (green) and posterior distributions after updating all the data (red) under two traffic conditions. The histograms represent the original GPS data.

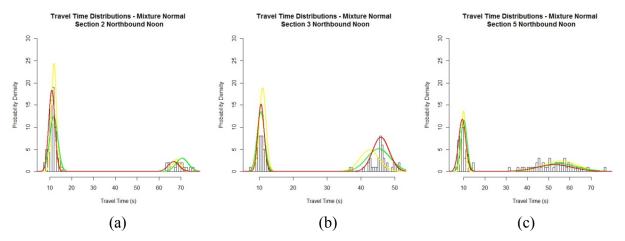

Figure 6-4 Comparison Among Prior and Posterior Distributions at Noon

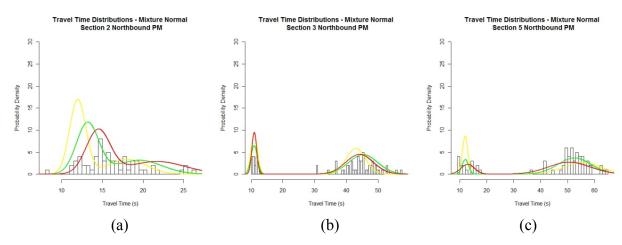

Figure 6-5 Comparison Among Prior and Posterior Distributions at PM

It can be seen from the figures that if the estimation of prior distribution is quite accurate such as Figure 6.4 (c), the posterior distribution doesn't differ very much from the prior. If the estimation of prior distribution is not good such as Figure 6.5 (a), the posterior distributions tend to pull the prior distribution in the right direction. If more data are used, then the posterior distribution should become more accurate.

The posterior distributions after updating with all data are compared with results from EM algorithm as shown in Figure 6.6 and Figure 6.7. The red curve represents posterior distribution from Bayesian update and the blue curve represents distributions estimated from EM algorithm.

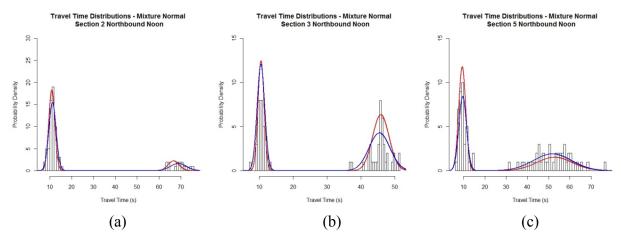

Figure 6-6 Comparison Between Bayesian Update and EM Algorithm at Noon

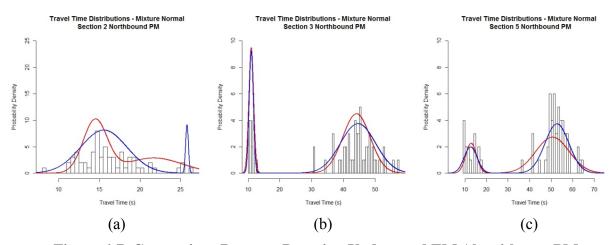

Figure 6-7 Comparison Between Bayesian Update and EM Algorithm at PM

From the previous two figures, it can be seen that the Bayesian update and EM algorithm achieved similar results except Section 2 at PM (Figure 6.7 c). In this case, the EM algorithm indicates that the two components are separated because there is no data in between. However, the Bayesian posterior distribution says the two components are mixed and the high probabilities between the two components (around 21 to 24 second) imply some data are missing. If we take a look at the time space diagram of Section 2 at PM as shown in Figure 6.8, the Bayesian result is more convincing.

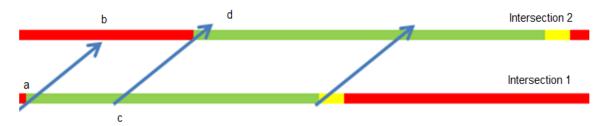

Figure 6-8 Time Space Diagram of Section 2 at PM

The arterial link between Intersection 1 and Intersection 2 are noted as section 2. If a vehicle passes Intersection 1 at the beginning of green phase at time point a and arrives Intersection 2 at time point b, it will experience signal delay from time point b to time point d, the end of red phase. If a vehicle passes Intersection 1 at time point c and arrives Intersection 2 at time point d when the green phase of Intersection 2 just begins, it becomes a non-stopped vehicle. Vehicles passing Intersection 1 between time point a and c experience signal delay which gradually decreases from a to c. In other words, the signal delay time gradually decreases to zero from d-b and thus there should be no obvious gap between non-stopped and stopped vehicles. The posterior distribution could capture this phenomenon because the Bayesian update combines information from data, and from the prior distribution which is estimated from signal time information.

In addition, Kolmogorov-Smirnov test (Ross, 2004) is run to test the goodness of fit to both EM and Bayesian models. The results are shown in Table 6.7 and Table 6.8. D statistic expresses the distance between the empirical cdf and theoretical cdf and P-value expresses the probability to accept the null hypothesis that the data are drawn from the theoretical distribution. Both the D statistic and p-value show in all circumstances EM fits the data better than Bayesian update. That is because EM is purely based on the data, while the Bayes estimate also incorporates prior information. In addition, the traffic condition identification or data classification process may put the data into wrong traffic condition. Although the error rate is low, still some data are wrongly updated. However, as stated in the previous paragraph, sometime Bayesian approach could reflect the real world situation when some data is missing while frequentist (EM) did not.

Table 6-7 D-statistic of Each Section under Different Traffic Condition

K-S test D statistic	Section Noon	2	Section Noon	3	Section Noon	5	Section PM	2	Section PM	3	Section PM	5
EM	0.0649		0.0797		0.0613		0.0695		0.0745		0.0807	
Bayesian	0.1356		0.0926		0.1303		0.1770		0.1065		0.8079

Chapter 7 A Case Study – Washington Avenue

In this chapter, a case study utilizing data collected from probe vehicles equipped with a GPS are demonstrated first. Then a microscopic simulation model is set up and calibrated to acquire sufficient travel time data to test the methodologies developed in the previous chapters. This case study focuses on one arterial segment of Washington Avenue near the East Bank Campus of University of Minnesota at Twin Cities. The segment includes arterial links on Washington Avenue from Oak Street to the entrance of the Washington Avenue Bridge, in both westbound and eastbound directions as shown in Figure 7.1.

Figure 7-1 Washington Avenue Satellite Image (Source: Google Earth)
© Google

In order to better illustrate the geometry, a schematic of this arterial segment is shown in Figure 7.2. All links and intersections are labeled by unique identification numbers. The arterial segment consists of 5 links and intersections in each direction. Of the five intersections, only Intersection 415 is un-signalized.

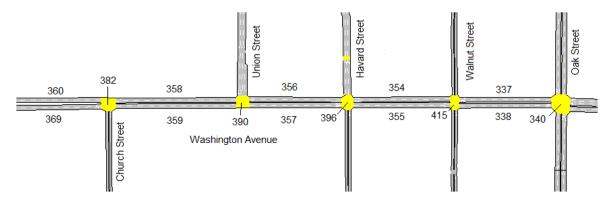

Figure 7-2 Washington Avenue Segment Schematic with Identification Numbers

7.1 Implementation Based on Real GPS Information

The GPS travel time data used in this case study was collected to ascertain the traffic flow pattern changes resulting from the opening of the replacement I-35W Mississippi River Bridge in September 2008. The data and the report in its entirety can be found in the Mn/DOT project "Traffic Flow and Road User Impacts of the Collapse of the I-35W Bridge over the Mississippi River"(Zhu et al. 2010). GPS devices were installed in commuters' vehicles to track travel time and routes. Most of the participants were staff of the University of Minnesota and they

commuted regularly to university for work. The data collection lasted for 13 weeks and more than 2,000 link travel times were collected.

Only travel times from through-through vehicles during weekdays are included in this case study. Successive links 369, 359 and 357 are used to construct an eastbound route and links 354, 356 and 358 are used to construct a westbound route. It is assumed that under different signal control plans, traffic conditions are different. Then, three different traffic conditions are defined in this case study: AM rush hour, mid-day and PM rush hour. Each direction of route contains data from two traffic conditions out of the three. The eastbound route contains AM rush hour and mid-day traffic conditions and the westbound route contains PM rush hour and mid-day traffic conditions. The underlying reason is most GPS vehicles came from the Washington Avenue Bridge eastbound and went to the university campus for work in the morning and went back home from university in the evening.

According to the signal-timing plans, periods from 6:00AM to 8:45AM, 8:45AM to 2:45PM, and 2:45PM to 6:15PM constituted the AM, Mid-day, and PM peaks respectively. Then the GPS data was classified into different traffic conditions by their trip times. For eastbound vehicles, 31 GPS travel time sequences were collected during AM rush hour and 23 GPS travel time sequences were collected during mid-day. For westbound vehicles, 30 GPS travel time sequences were collected during PM rush hour and 15 GPS travel time sequences were collected during mid-day.

The travel time distributions can be approximated by mixture normal densities using EM algorithm. The approximated mixture normal distributions for westbound route (link 354, link 356 and link 358) under mid-day and PM rush hour are shown in Figure 7.3 and Figure 7.4 respectively.

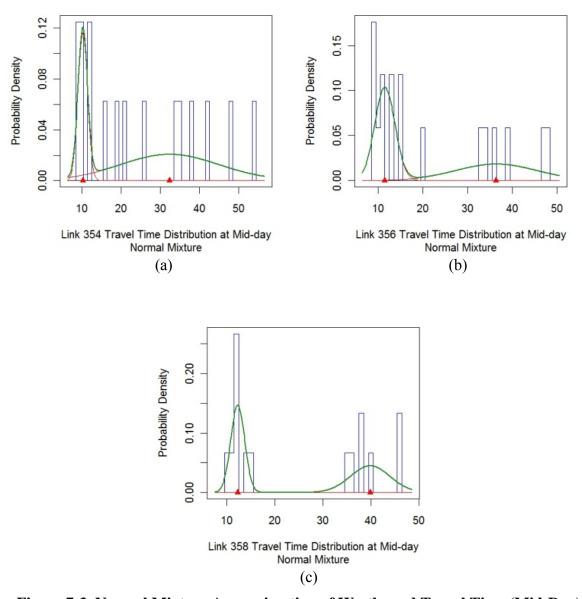

Figure 7-3 Normal Mixture Approximation of Westbound Travel Time (Mid-Day)

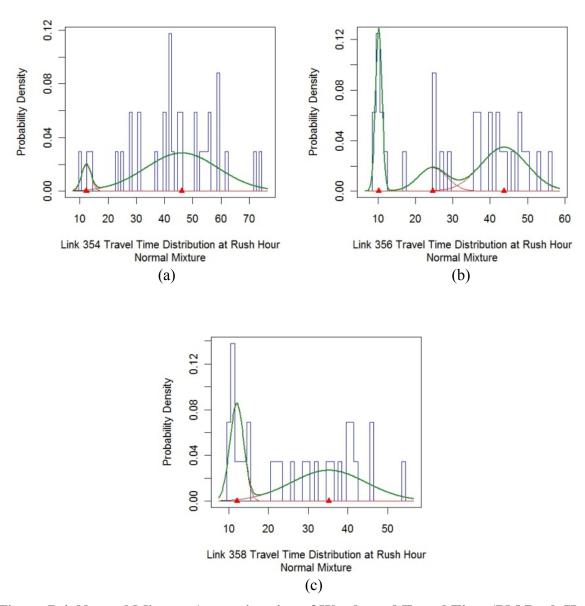

Figure 7-4 Normal Mixture Approximation of Westbound Travel Time (PM Rush Hour)

The approximated mixture normal densities for eastbound route (link 369, link 359 and link 357) under mid-day and AM rush hour are shown in Figure 7.5 and Figure 7.6 respectively.

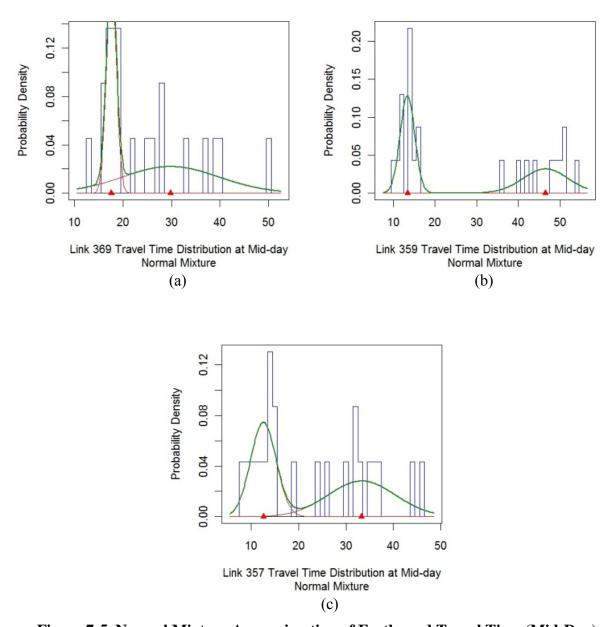

Figure 7-5 Normal Mixture Approximation of Eastbound Travel Time (Mid-Day)

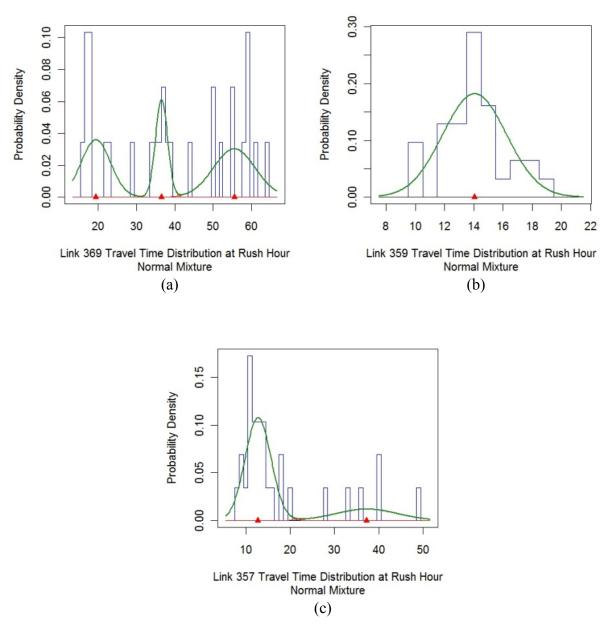

Figure 7-6 Normal Mixture Approximation of Eastbound Travel Time (AM Rush Hour)

The real-time traffic condition identification is performed on both westbound and eastbound cases. Figure 7.7 shows the results.

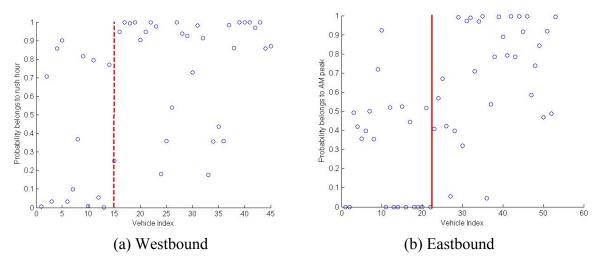

Figure 7-7 Traffic Condition Identification for Washington Avenue GPS Data

Figure 7.7 (a) shows the identification result for westbound travel time data. Each dot represents a vehicle; the dots on the left side of the vertical line are the vehicles from mid-day, and on the right side are the vehicles from PM rush hour. The figure shows that the identification result is not accurate for vehicles from mid-day traffic condition. For vehicles from the PM rush hour, most of the time the identification approach can classify the GPS to the right category. Figure 7.7 (b) shows the identification results for eastbound traffic. The dots on the left side of the vertical line are the vehicles from mid-day, and on right side are the vehicles from AM rush hour. The result is similar for the westbound case. It can be seen that the identification result in rush hour is better than mid-day. The main reason is the sample size of GPS data under mid-day traffic condition is too small. For example, westbound route under mid-day condition only has 15 samples. It is very difficult to fit a mixture normal model (five parameters) with only 15 samples. The fitted distribution may not reflect the real world scenarios. By contrast, sample size for fitting PM rush hour traffic condition is larger (30 vehicles) which makes the distribution more accurate. As a result, the identification process could classify more data accurately.

The current traffic condition identification approach, as shown in Figure 7.7 (a) and Figure 7.7 (b), actually shows the probability of a GPS travel time sequence that belongs to a known traffic condition. However, if a GPS travel time sequence comes from an unknown traffic condition, the current identification approach would be unable to recognize it.

Equation 5.5 shows the probability that a GPS travel time sequence belongs to one particular traffic condition is rather a ratio of two probabilities than an actual probability. For example, in the case shown in Figure 7.7 (a), if the ratio is high, it means the probability that a GPS travel time sequence belongs to the rush hour distribution is much higher than the probability this sequence belongs to it's mid-day counterpart. If a GPS travel time comes from an unknown traffic condition, both the probabilities may be very low. However, the ratio must still be between zero and one.

This gives us a clue to identify a new traffic condition using actual probabilities. That is, if actual probabilities that belong to all existing traffic conditions are below a threshold, it might suggest this GPS vehicle is from a new traffic condition.

It is shown in Equation 5.4 that the probability that a GPS travel time sequence belongs to a certain route, is the product of the probabilities that each link travel time belongs to each link travel time distribution. Each link probability is calculated as the ratio of probability density of the distribution function. For example, the travel time of non-stop vehicles follows a normal distribution N(10,1). If the travel time is 10 second, then the probability that this travel time belongs to this distribution is 1. If the travel time is 11.96 second which is the approximately 95th percentile of the distribution, then the ratio is 0.05. For the general case, if the travel time is beyond the 99th percentile which is equal to the ratio is smaller than 0.01, then it is considered not to belong to this link travel time distribution. In Washington Avenue case, the route consists of three consecutive links. Therefore, the threshold could be set to $0.01 \times 0.01 \times 0.01 = 10^{-6}$. That means if both of the probabilities belong to either traffic condition (PM rush hour or mid-day) are smaller than 10^{-6} , then this GPS data is considered to be from a new traffic condition.

To illustrate this idea, an example based on Washington Avenue westbound GPS data is provided. Figure 7.8 shows the results. The value of the Y-axis is the probability after taking \log_{10} of the original probability. Consequently, 10^{-6} is equals to -6 which is the threshold.

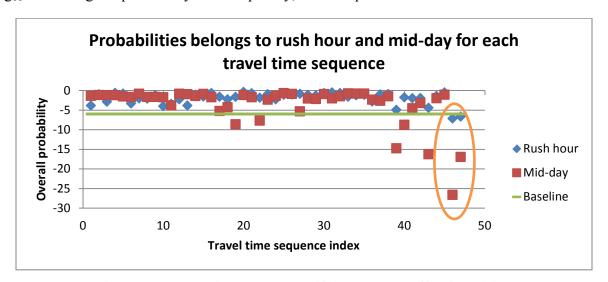

Figure 7-8 Experiment on Identifying New Traffic Condition

In Figure 7.8, the first 45 travel time sequences are either from mid-day or PM rush hour traffic condition. The last two sequences (in the orange circle) are from an unknown traffic condition. The diamond shape indicates that the travel time probably belongs to rush hour, and the rectangle shape denotes a mid-day travel time. It can be seen from the figure that for travel time sequences from known traffic conditions, there is no case that both probabilities are below the threshold. However, for the last two travel time sequences, both probabilities are below the threshold.

Note that in Figure 7.4 (b) and Figure 7.6 (a), during rush hour more than two peaks are identified. The third peak represents the vehicles that stopped twice which only happens under an oversaturated condition. Therefore, travel time distributions in Figure 7.4 (b) and Figure 7.6 (a)

contains two different traffic conditions: under-saturated (first and second peak) and oversaturated (second and third peak). Take Figure 7.6 (a) as an example, all travel time data were collected during morning peak when the signal control doesn't change. That means only traffic demand creates different traffic conditions, and subsequently travel times. Unfortunately, the real-time traffic demand on Washington Avenue can't be obtained directly because there is no monitoring system. The volume information from the loop detectors on I-35W is used to reflect the demand of Washington Avenue eastbound direction.

The detectors (2133 and 2134) are located at the ramp exiting to Washington Avenue as shown in Figure 7.9. Although the ramp has other exits than Washington Avenue eastbound, it is assumed that the traffic volume on the ramp is a portion of total volume on Washington Avenue, and that the overall daily trends are consistent. The volume information from August, 2008 to December, 2008, which is the same time period when the GPS data was collected, is then downloaded from MnDOT Data Extract Tool.

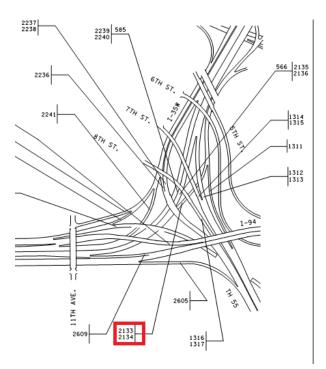

Figure 7-9 Detector used to Represent Traffic Volume on Washington Avenue

Source: All Detector Report, MnDOT. Updated March 2011

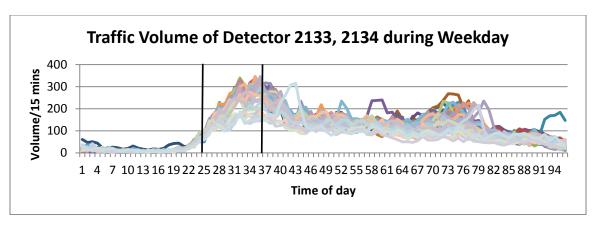

Figure 7-10 Traffic Volume of Detector 2133, 2134 during GPS Data Collection Period

Figure 7.10 shows the variation of traffic volumes of detector 2133 and 2134 within a day during the GPS data collection period (Aug, 2008 to Dec, 2008). The volumes are aggregated every 15 minutes and each broken line represents one day. As a result, there are 96 segments in one day. It can be seen from the figure that during the morning peak hour (between two black lines), the volume varies a lot. Using the date and time as an index, it was possible to look at the GPS data in conjunction with the volume data provided by the ramp detectors. If the volume is high at a certain time of a day and the corresponding travel time is also long, then travel time data can be categorized accordingly. Figure 7.11 shows the match of travel time and traffic volume.

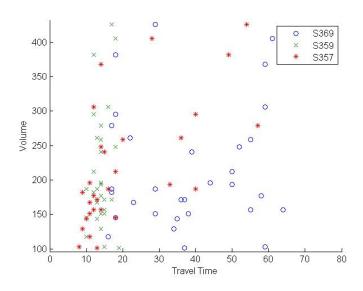

Figure 7-11 Match of Volume and Travel Time

Figure 7.11 shows the match of volume and travel time during AM peak hour on Washington Avenue eastbound. Different colors/shapes represent travel times from different arterial links. Unfortunately, it does not show a clear pattern that higher volume results in longer travel time. One possible reason is that the volume on freeway ramps doesn't have a direct correlation with the volume on Washington Avenue also it is possible that the conditions on Washington avenue are the result of evolving conditions and therefore travel times will not have a direct correlation with the ramp volumes. The limited GPS sample data that we had available do not allow us to

investigate the evolution of travel time along with the evolution of ramp volume. As such, higher volumes of GPS equipped vehicles needed to be simulated to identify different traffic conditions. To achieve this, an AIMSUN microscopic simulation model is built.

7.2 AIMSUN Simulation Model of Washington Avenue

Although the dataset was large, and covered the area for the analysis, preliminary testing showed that there was insufficient data to determine the unique travel time distributions. This meant it was necessary to find a means to enlarge the data set. The most appropriate tool in this case was to create a microscopic simulation model of Washington Avenue. A microscopic model accurately simulates driver behavior, so a properly calibrated network will exhibit the trends that this methodology is trying to expose.

Although the data from the NGSIM project was sufficient for testing the methodology on Peachtree Street, this was not the case with the GPS data set for Washington Avenue. As such, a microscopic simulation network was necessary. To create the simulation network, information for the geometry, demand, and control were necessary. All three of these things were used to create a network that simulated reality as closely as possible.

The first thing necessary was to code the network geometry for Washington Avenue. This was accomplished using ortho-rectified maps of the area provided by USGS, as well as information from the city of Minneapolis. This consisted of coding the basic roadway network, in addition to lateral lanes, signal and stop controlled intersection placement, centroid coding, and minor adjustments to insure that vehicles behaved correctly in the network during simulation. Figure 5-12 presents a top-down view of most of the modeled network. The colored circles represent the Origin/Destination centroids while the signalized intersections can be seen in yellow. The segment of Washington Ave used in this work is circled. It is easy to see that the network contains much more than just Washington Avenue, unlike to the Peachtree Street Network. This is the case because on Peachtree Street, there was perfect knowledge of the boundary conditions. However, with Washington Avenue it was necessary to expand the model such that, the vehicles arriving at the edges of Washington Avenue would be doing so in a way that was similar to reality. Thus the addition of University Avenue to Highway 280, Huron Avenue to I-94, and many of the arterials in the surrounding area was necessary.

The next aspect that is crucial to any microscopic model (especially one containing urban arterials) is proper implementation of the control. To program the signals, timings were obtained from the Minneapolis Traffic Engineer. These timing plans consisted of 4 fixed timing plans that are activated for off-peak, peak (AM and PM), and mid-day periods. These timing plans were then programmed manually for the 40 signals that exist in the network extents. Once they were programmed, they were verified to ensure that they provided a perfect emulation of the control.

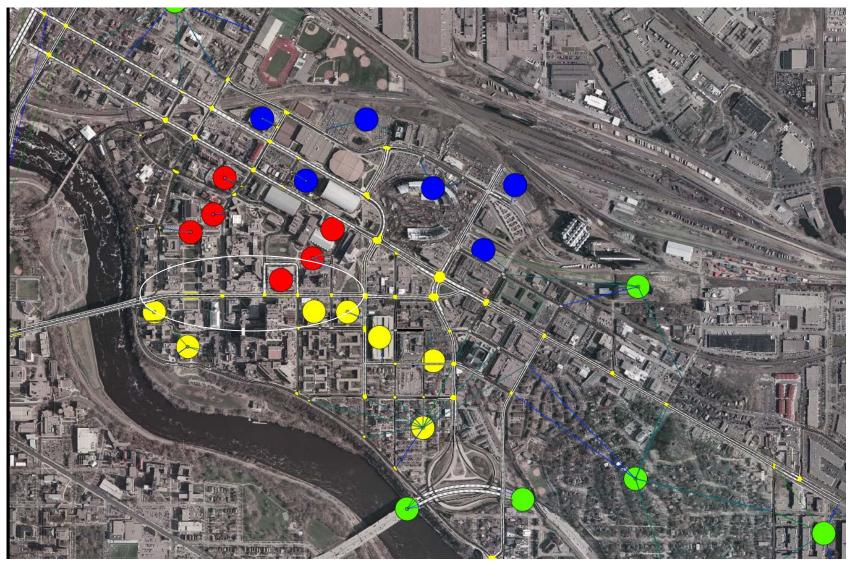

Figure 7-12 Microsimulation Network Model of Washington Ave Area

To calibrate the model, the last aspect of the network that needed to be included was the demand. The demand was derived from the regional macroscopic model developed by the Metropolitan Council. Here the macroscopic model's output didn't have enough information for the microscopic model demand, which meant that a process of adjustment and enrichment needed to happen so that it would be suitable for simulation. This is often the case, and usually it means using traffic sensors that are in the model area to adjust the demand supplied by the more general network. However, in this case the data provided by conventional sensors (loop detectors, radar installations, etc.) were not sufficient to perform a valid adjustment. For the adjustment to be valid, it is necessary that the detectors cover 90% of the trips that traverse the network. Thus it was necessary to supplement the data with additional sources. The University of Minnesota has thousands of employees, who come and go from the campus every day, necessitating ample parking facilities. To validate the existence of these facilities, careful records of usage are kept by parking management staff. To be able to utilize this data, modification of the existing origindestination tables was necessary. The regional model grouped the entire sub-area into three origin-destination nodes, which was insufficient for the level of fidelity required of the network. It was decided that the table would be further split using the parking facilities as sub-nodes. To adjust the table volumes a scaling factor was necessary. The capacities of the parking facilities provided this. The result was a new origin-destination table that had every major parking facility on the campus as a row and column in the demand table.

Once the origin-destination table had been enriched, it was still necessary to adjust the demand. As stated previously, the sensors in the sub-area were insufficient to perform an adjustment, and adding nodes only exacerbated the problem. The data provided by the University of Minnesota Parking Services for facility performance includes input and output flows every 15 minutes. This data then represents a set of ad hoc detectors within the boundaries of the simulation network. Since in this case many of the vehicles that enter the network area, stay in the area (and vice versa), this new set of detectors are very valuable (as they capture many of the trips).

Calibration of the simulation network

Despite the fact that the data was insufficient on its own to test the methodology, it was utilized to apply a novel calibration methodology for the network. In this technique, aggregate travel time distributions are created as a metric for tuning the driver behavior parameters in the underlying models. The GPS data that was provided by [Zhu 2008], was from a study that was attempting to determine the changes in travel patterns as a result of the collapse of the I-35W bridge. It came in the form of several months' worth of GPS trips for several drivers working in and around the University of Minnesota-Twin Cities campus. To make these distributions it was necessary to filter the GPS data to determine section travel times.

For the data set that was being used, there were several vehicles, with several trips. For each trip that used Washington Avenue, travel time data was collected. To determine the travel time for a given section in the network, the two points in the trip that were closest to the center of the respective from and to nodes were used. The difference in time at each of these points was taken, and the result was the time it took for the vehicle to traverse the section. To do this filtering, a database of all the GPS points was extracted, and a python script was utilized to make the calculations.

Once the travel times had been extracted from the GPS data, it was possible to create cumulative distributions of the data. This was done by combining all travel times by time of day in hourly increments. This data was then used in the calibration process. To do this, a metaheuristic optimization was performed. The objective function for the optimization was the D-statistic from the Kolmogorov-Smirnov test. The D-statistic measures the maximum distance between two cumulative distributions. In terms of an optimization driver, the smaller the D-statistic, the better the solution. The calibration technique that was used in this process was unique and not pertinent to this projects work, as such, further detail is provided in Collins 2011. It was shown in [Collins 2011], that this approach provided a good calibration result, and that this calibrated network represented a good basis for the analysis being done. Once the calibration was completed it was possible to produce travel time distributions in a manner similar to the NGSIM data since every vehicle is a GPS probe. This way it is possible to evaluate how many GPS probes are necessary to produce useful information. The results of this analysis are shown in the following sections.

7.3 Travel Time Analysis Using Simulation Data

Travel times of through-through vehicles from eastbound links 359, 357, 355 and 338 during AM peak hour are selected from AIMSUN simulation. Since intersection 415 is un-signalized, link 355 and link 338 are considered as one link. Figure 7-13, Figure 7-14, and Figure 7-15 show the travel time histograms of link 359, 357, 355 respectively. The histograms contain travel time during the whole morning peak. (6:00AM – 8:45AM)

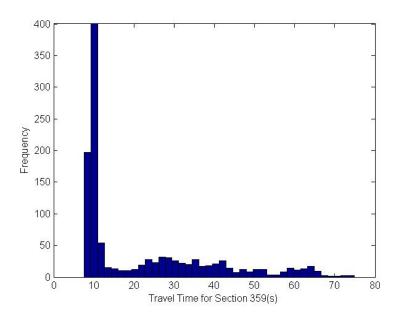

Figure 7-13 Travel Time Histogram of Link 359

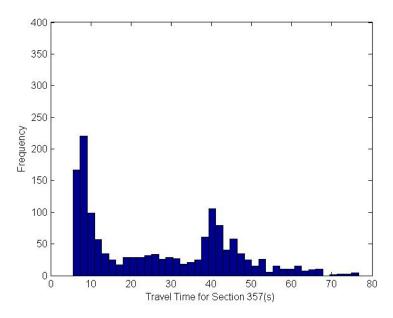

Figure 7-14 Travel Time Histogram of Link 357

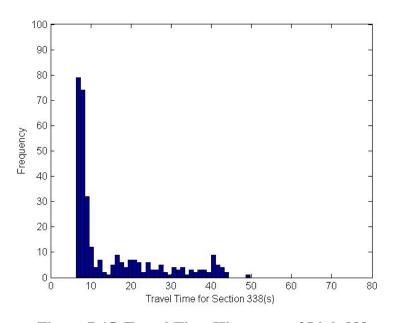

Figure 7-15 Travel Time Histogram of Link 338

It can be seen from Figure 7-13 that the travel time histogram has three components implying multiple traffic conditions. In order to differentiate travel times under different traffic volume, travel times are then plotted with time of the day (in seconds) as shown in Figure 0-16, Figure 7-17 and Figure 7-18. Note that traffic volumes vary with time. So Figure 7-16 through Figure 7-18 could be also considered the representation of the relationship between travel time and traffic volume.

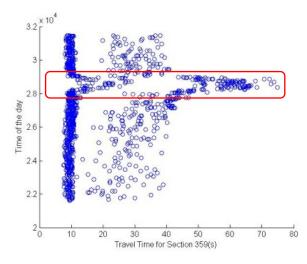

Figure 7-16 Differentiate Travel Time by Time of the Day (Link 359)

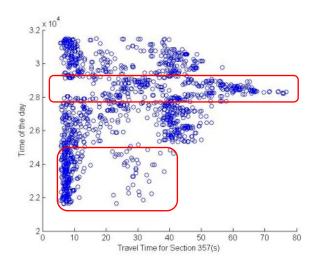

Figure 7-17 Differentiate Travel Time by Time of the Day (Link 357)

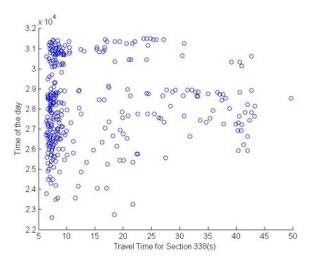

Figure 7-18 Differentiate Travel Time by Time of the Day (Link 338)

For example, in Figure 7-16, the travel times inside and outside of the red rectangle clearly show different patterns. The travel time outside the red rectangle represents a non-oversaturated traffic condition where left part (around 10 seconds) indicates non-stopped vehicles and the right part (20 – 40 seconds) indicates stopped vehicles. The average travel time of non-stopped vehicles is close to the free flow travel time. The travel time inside the red rectangle represents the oversaturated traffic condition where there is very few free flow travel times. Meanwhile, travel times from 55 seconds to 80 seconds imply that those vehicles stopped twice. Consequently, two different traffic conditions are identified. Similar as Figure 7-16, Figure 7-17 identifies three different traffic conditions for link 357. For link 338 as shown in Figure 7-18, only one traffic condition can be recognized.

Travel time histograms of each link are then split according to different traffic conditions identified from Figure 7-16 to Figure 7-18. Figure 7-19, Figure 7-20 shows the travel time histograms of different traffic conditions for link 359, link 357 respectively. Since link 338 only has one traffic condition during morning peak, it is not necessary to split it into different parts.

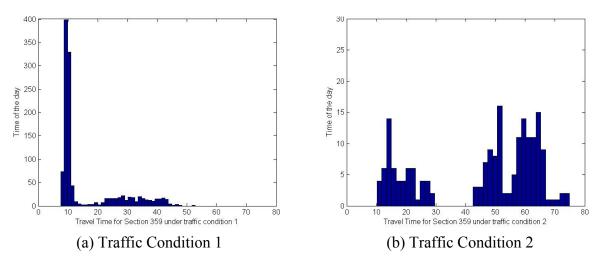

Figure 7-19 Travel Time Histogram of Link 359 under Different Traffic Conditions

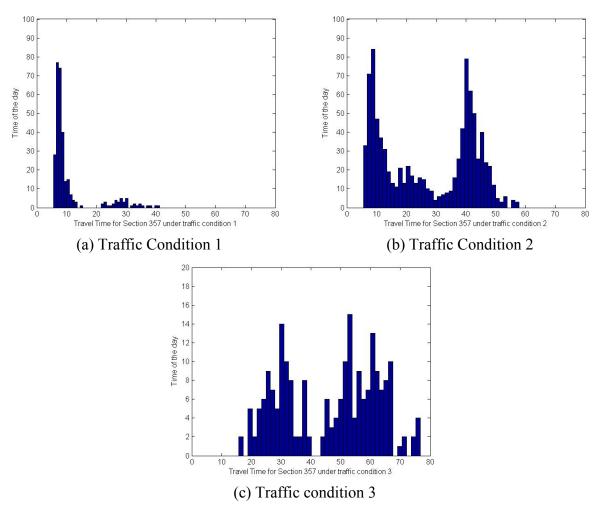

Figure 7-20 Travel Time Histogram of Link 357 under Different Traffic Conditions

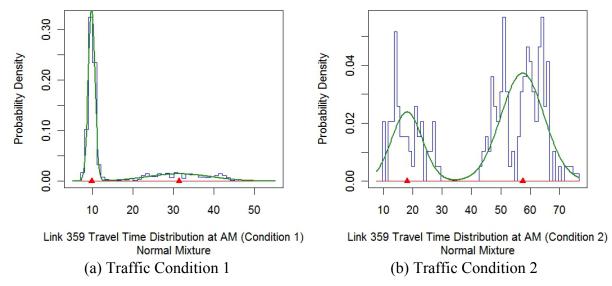

Figure 7-21 Mixture Normal Approximation of Travel Time of Link 359 under Different Traffic Conditions

Now mixture normal densities can be used to approximate the histograms shown in Figure 7-19, Figure 7-20 and Figure 7-15. The results are shown in Figure 7-21, Figure 7-22 and Figure 7-23.

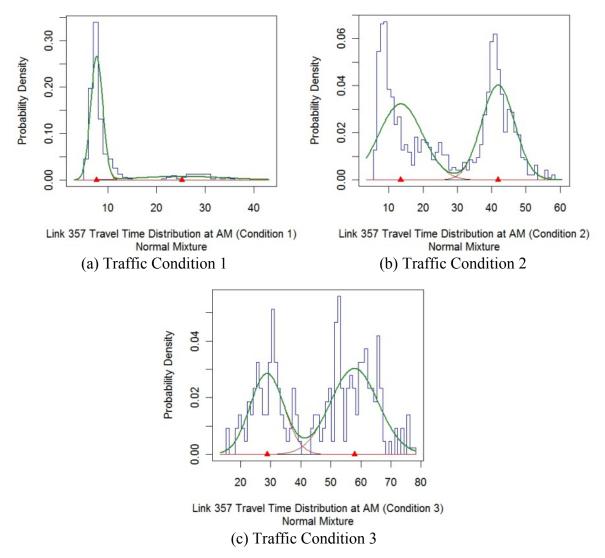

Figure 7-22 Mixture Normal Approximation of Travel Time of Link 357 under Different Traffic Conditions

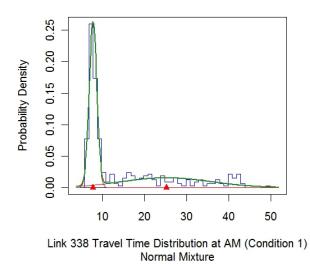

Figure 7-23 Mixture Normal Approximation of Travel Time of Link 338

The traffic conditions for the route during morning peak hour are divided into three parts by time. Route traffic condition 1 consists of travel times from 6:00AM to 7:00AM (21600s – 25200s). Route traffic condition 2 consists of travel times from 7:00AM to 7:48AM (25200s – 28100s) and 8:03AM to 8:45AM (29000s – 31500s). Route traffic condition 3 consists of travel times from 7:48AM to 8:03AM. (28100s – 29000s). Each route traffic condition is a combination of different link traffic conditions, and the relationship between route traffic conditions and link traffic conditions is shown by Table 7.1.

Table 7-1 Relationship between Route Traffic Conditions and Link Traffic Conditions

Route TC	Link 359 TC	Link 357 TC	Link 338 TC
1	1	1	1
2	1	2	1
3	2	3	1

The real-time traffic condition identification is performed for the morning peak hour. Only vehicles that pass through the whole route are selected. In Total, there are 302 vehicles representing 2 hours and 45 minutes. There are 16, 220, and 66 vehicles from traffic conditions 1, 2, and 3 respectively. The identification result is shown in Figure 7-24.

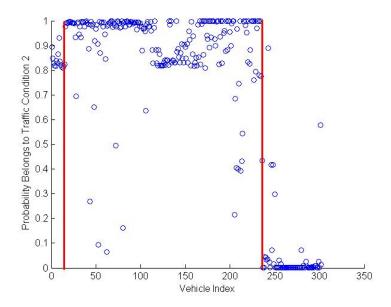

Figure 7-24 Traffic Condition Identification during Morning Peak (3 Conditions)

Each of the dots on the left part represents a vehicle from traffic condition 1, the dots in the middle are vehicles from traffic condition 2, and on the right are the vehicles from traffic condition 3. The figure shows that generally, traffic condition 2 and traffic condition 3 are noticeably different. However, discriminating between traffic condition 2 and traffic condition 1 is difficult in this case. The reason is that two link travel time distributions are different (Link 359 and Link 357) when discriminating traffic condition 2 and traffic condition 3, but there is only one link travel time distribution different (Link 357) when discriminating traffic condition 1 and traffic condition 2. The more differences there are in link travel time distributions, the easier to distinguish different traffic conditions. This suggests that two traffic conditions during morning peak may be sufficient to characterize the changing traffic volume.

This analysis suggests two things. First, there is a reliable way of correlating individual GPS probe travel times with travel time distributions describing a specific traffic condition. This allows, as described earlier in this document, to improve the historical TT distributions with the acquisition of new GPS probe information. Second, in a mature system, given a small amount of GPS probe information we can reliably determine the active traffic conditions and estimate travel time for the route for use in performance monitoring, and traffic information systems. For example, given the information in the aforementioned illustration, with only a few GPS probe trajectories, one can determine in real time if the average travel time is around 10 sec (TC 2) or between 30 sec and 60 sec (TC3).

Chapter 8 Conclusions and Further Research

8.1 Conclusions

The original objective of this project was to utilize GPS probe data to provide estimates of arterial travel times. On a theoretical basis such a goal is not impossible but it quickly became apparent that it is not efficient. As discussed in the literature, to produce reliable travel times on every location of the network at any time of the day a high density of probe vehicles is required. This is the pitfall of all currently available commercial products offering real-time travel times on arterial. They either cover a small piece of the network or their results are not accurate. This project could have operated under the assumption that in reasonable period of time vehicle fleet technology will advance to the point of having high density of probe data. Since it is unclear how and when this will happen in the future a different path was selected. Specifically, this project aimed at a cooperative approach in travel time estimation using static information describing arterial geometry and signal timing information, semi-dynamic information of historical travel time distributions per time of day, and utilizes GPS probe information to augment and improve the latter. The objectives of this study focused on developing a methodology to characterize arterial travel time patterns by travel time distributions, propose methods for estimating such distributions from static information and refining them with the use of historical GPS probe information, and given such time and location-based distribution use real-time GPS probe information to produce accurate path travel times as well as monitor arterial traffic conditions.

First, travel time patterns of signalized arterial links were analyzed based on travel time histograms. The report mainly focused on through-through vehicles. From this subset of vehicles, four travel time states were defined: non-stopped, non-stopped with delay, stopped, and stopped with delay. Second, link travel time distributions were approximated using mixtures of normal densities. According to the definition of travel time states, two approaches to estimate travel time distributions were proposed. If prior travel time data is available, travel time distributions can be estimated empirically, using the EM algorithm. Otherwise, travel time distribution can be estimated based on signal timing information and geometric structure of the arterial. Third, link travel time was extended to produce route travel times. Because travel times on successive links are not independent, a Markov Chain based model was proposed to capture the potential relationship of travel time between consecutive links. Empirical examples showed the estimated route travel time by the Markov Chain model was very accurate with errors less than 2%.

GPS travel time data is used to predict the travel time by identifying the traffic condition. The traffic condition identification approach was developed based on Bayes Theorem. Results showed that in most cases, one GPS sample was enough to discriminate between the two traffic conditions. Compared to other approaches, the proposed method needs much less real-time information. Moreover, these GPS data could also be used to update the parameters of the travel time distributions using a Bayesian update. The iterative update process makes the posterior travel time distributions more and more accurate.

Finally, two comprehensive case studies using the NGSIM Peachtree Street dataset and GPS and simulation data of Washington Avenue were conducted. The first case study estimated prior

travel time distributions based on signal timing and geometric structure under different traffic conditions. Then, travel time data were classified into different traffic conditions and corresponding distributions were updated. In addition, results from the Bayesian update and EM algorithm were compared. Overall, the EM algorithm fit the data better than Bayesian update. However, in some scenarios the Bayesian approach could reflect the real world situation when some data was missing.

The second case study first tested the methodologies based on real GPS data collected for studying the traffic flow pattern change of the opening of the replacement I-35W Mississippi River Bridge. After which, a methodology was proposed to distinguish new traffic conditions. In order to differentiate traffic conditions under same signal control by volume, a microscopic simulation model was built. Utilizing the data collected from simulation, three different traffic conditions were identified during morning peak hour.

8.2 Further research

This report lays a foundation for the characterization of travel time distributions on urban arterials. Future research will need to address the following issues:

- The current research focuses on through-through vehicles. Turning vehicles have more
 complicated travel time states. Therefore, turning vehicles must necessarily be further
 divided into sub categories and each category represents only a special scenario of
 turning. For example, right turn from side streets, which go through at the downstream
 intersection.
- Estimating travel time distributions in oversaturated conditions. When the traffic is congested and queues can't be discharged within one cycle, the bimodal pattern may not be applicable and more travel time states are expected. For example, the vehicles that stopped twice for red signal would generate a new state. Meanwhile, the estimation of travel time based on signal time and geometric structure needs to be modified accordingly.
- Capitalize on the findings of this project to develop a dynamic signal control methodology. So far most of the signal control is pre-timed, and changes according to the time of the day. The reason behind this scheme is based on the assumption that traffic volume patterns remain relatively consistent. However, it is not always true. For example, a football game at weekend may cause the traffic condition to be similar as peak hour at weekdays. It is better to implement peak hour signal control plan than off-peak (weekend) signal control plan. If the real-time traffic condition is known, signal control plan can be selected dynamically to minimize the delay.

The vision for the future can be described as follows. The traffic management authority of a large metropolitan area maintains a GIS database of all the signalized intersection time plans in the network. Based on the methodology described in this work, prior distributions of travel times for all arterial streets are generated for each period of the day a different signal plan is in effect. If there are already available historical travel times from probe vehicles they can be used as described in this work to generate the aforementioned prior distributions. Using the Bayesian Update methodology described in this work, new travel time information are used to continually improve the arterial street travel time distributions. Initially, these distributions will be few and

will not be able to describe transitional conditions experienced during peak periods of the day. Eventually, though the GPS probe information will help separate the distinctly different travel time distributions that describe distinctly different traffic conditions. As soon as this point is achieved, which could vary for each arterial street but should not take long, new GPs probe information will be used to identify the present traffic conditions and alert the authority when the conditions are not the expected for the particular time of day. In effect, the system will be able to provide real-time information of arterial street traffic conditions as well as serve as an incident detection mechanism signaling the development of an unexpected traffic condition.
